# # 5672886523 : MAJOR GEOLOGY

KEYWORD: structural geology, rift basin, reservoir characterization, seismic attributes, fluvial, depositional environments

Jidapa Phoosongsee: THE INFLUENCE OF GEOLOGICAL STRUCTURE ON STRATIGRAPHIC DEVELOPMENT DURING MULTIPHASE RIFTING IN THE SONGKHLA BASIN, GULF OF THAILAND: Advisor: Assoc. Prof. Thasinee Charoentitirat, Ph.D. Co-Advisor Christopher K. Morley, Ph.D.

The Cenozoic N-S trending Songkhla rift basin, located in the southwest Gulf of Thailand, was developed as a predominantly orthogonal extended half graben structure. The half graben is controlled by a boundary fault zone on the western side of the basin, which forms a series of N-S to NNE-SSW, east-dipping normal faults. The rift spans two phases of rifting; the Eocene-Oligocene and the Oligocene-Miocene phases, the late syn-rift to post-rift transition occurred from the late Early Miocene to Middle Miocene. The main clastic hydrocarbon reservoirs in the basin are located in the Early Miocene to Middle Miocene section. These reservoirs are predominantly fluvial channels with complex lateral and vertical geometries and distributions particularly as point bars, overbank deposits, and sand- or mud-filled channels. This study characterizes the reservoir architecture and depositional environment of the Songkhla Basin from the late syn-rift to post-rift by integrating the seismic attributes (RMS, similarity, and spectral decomposition), well log interpretations, and well biostratigraphic data. Two distinctive channel characteristics and patterns were interpreted: (A) N-S oriented meandering channel complexes, aligned sub-parallel to the western boundary faults, developed during the late syn-rift (upper Early Miocene) and (B) NE-SW oriented long, narrow fluvial channels with tidal and marine influence, developed in the post-rift phase I (Middle Miocene). These channel orientations reflect changes in the basin architecture passing from the late syn-rift stage to the post-rift. Syn-rift channel orientation was controlled by topography created by motion on the western boundary fault system, while the post-rift the channel orientations were affected by mild inversion on the boundary fault system and thermal subsidence, which resulted in an eastwards shift in the basin depocentre towards the flexural margin.

## ACKNOWLEDGEMENTS

I am very grateful to my advisors Dr. Christopher K. Morley and Associate Professor Dr. Thasinee Charoentitirat for their continued support, guidance and encouragement on completing my research study. I would like to extend my thanks to Dr. Joseph Lambiase, Mr. Angus J. Ferguson and Dr. John K. Warren for their useful discussions, comments, suggestions and helpful feedback to my dissertation.

My thanks and appreciation also go to Cepsa company for providing seismic reflection and well data, which are very crucial for my research work. I appreciate the helps from The Geology Department, Chulalongkorn University and The Department of Petroleum Geophysics for providing the opportunity for doing my research study and all the facilities required.

I especially thank the committee members Professor Dr. Montri Choowong, Associate Professor Dr. Pitsanupong Kanjanapayont, Dr. Sukonmeth Jitmahantakul, and Dr. Stefan Back for their discussions and feedback.

I am deeply thankful to Dr. Cheong Yaw Peng, my husband, for his patience and encouragement. Without his support, the completion of my study would not be possible. Especially thanks to Sukanlaya Jaruchaikul and Thidarat Cotanont for their camaraderie and blessing.

Jidapa Phoosongsee

# CHAPTER I

## INTRODUCTION

### 1.1 Thesis overview and structure

This thesis investigates the structural development and the reservoir distribution and deposition within the Songkhla intra continental rift basin, particularly from the late syn-rift to post-rift period (late Early Miocene to Middle Miocene), by using 2D and 3D seismic reflection data integrated with all available well log and biostratigraphic data. To unravel the tectono-stratigraphic evolution from the late syn-rift to post-rift period, several techniques have been applied, i.e., throw-length analysis, seismic attributes analysis, and the rock physics analysis.

This thesis is subdivided into six chapters. **Chapter 1** is an introduction to outline the rationale and specific research areas. **Chapter 2** describes the data and methodology being applied to analysis the 2D and 3D seismic reflection data of Songkhla Basin. **Chapter 3** presents the regional geology and stratigraphic framework of Songkhla Basin. The main body of original research and the results are presented in **Chapter 4** and **Chapter 5**, which have been published as two separate papers (Phoosongsee and Morley, 2018). The key conclusions and recommendation are being summarized in **Chapter 6**.

### 1.2 Background and motivation

The simplest depiction of the syn-rift to post-rift transition in failed rifts is the McKenzie model (1978), where the effecting of rifting (i.e. crustal stretching) were modelled as being instantaneous. Subsequent post-rift thermal subsidence, arising from the consequences of (exponential) thermal decay of the syn-rift lithospheric thermal anomaly, and sediment loading leads to broad, saucer-shaped thermal subsidence. In the flexural cantilever model of syn-rift and post-rift subsidence, a phase of erosion where the syn-rift topography is removed prior to subsidence is an option (e.g. Kusznir et al., 1995; Roberts et al., 2013). These early models of the syn-rift to post-rift transition describe the basic processes involved, and include an unconformity between

the rifting and the thermal subsidence phase. It is now recognized that the syn-rift to post-rift transition is highly varied in failed rifts and the variability in this transition is related to several different factors including: continental versus marine depositional environments, elevation of the basin (i.e. intermontane, coastal plain, shallow water to deep water), and duration of the transition (e.g. abrupt, slow, pulsed) (e.g. Nottvedt et al., 1995; Morley, 1999; 2002; Gabrielsen et al., 2001; Zachariah et al., 2009; Morley and Racey, 2011; Scherer et al., 2015; Marin et al., 2018). These factors in turn are controlled by different variables affecting rifts, such as their geographic and tectonic position (e.g. Morley, 2002; Basile et al., 2013), sediment supply, climate (e.g. McKenzie, 1978; Prosser, 1993; Scherer et al., 2015; Marin et al., 2018), the amount of stretching (McKenzie, 1978), whether tectonic inversion occurred at the end of rifting (Basile et al., 2013), and the driving mechanisms of extension (Morley, 2002).

In the rift basins of Thailand, examples of syn-rift to post-rift transition across all the basic elevation scenarios can be found, from the intermontane basins in the north of Thailand, to the coastal plains-shallow marine environments of the Central Basin, Gulf of Thailand (GOT) and Andaman Sea shelf, to the deep marine setting of the East Andaman Basin (see review in Morley et al., 2011). The variable timing of rifting events means that the end of rifting and onset of post-rift subsidence changes laterally within the Thailand Rift basins, but a general trend is for the syn-rift to post-rift transition to young northwards (Morley and Racey, 2011; Morley et al., 2011). Exposure in a sub-areal setting means that the syn-rift topography will be considerably eroded before post-rift subsidence occurs. Whereas a deep marine environment will preserve much of the syn-rift topography, which provides accommodation space for post-rift sediment to infill prior to the onset of thermal subsidence (e.g. North Sea) (Prosser, 1993; Gabrielsen et al., 2001; Zachariah et al., 2009; Marin et al., 2019). The coastal-shallow marine environment falls between extremes, and can exhibit continuity of deposition in the deeper parts of some basins, while undergoing considerable erosion of the syn-rift topography elsewhere. In this paper, we investigate the variations in the depositional environments between the syn-rift and post-rift sections in the Songkhla Basin, GOT. At the time of the transition, the basin lay in a coastal-transitional marine setting, and today the basin lies in water depths of less than 25 meters.

Fluvial reservoirs are the major hydrocarbon reservoirs in the GOT, which were deposited throughout the syn-rift and post-rift periods, ranging from Oligocene to Miocene sequences. These fluvial deposits interfinger with tidal and marine deposits, particularly in the Neogene section (see review in Morley and Racey, 2011). In general, the sands deposited in fluvial depositional systems have complex lateral and vertical geometries and distributions as they contain a series of point bars, overbank deposits, and sand- or mud-filled abandonment channels (Ahmad and Rowell, 2014; Jardine, 1997; Lockhart et al., 1997). Regarding this complexity, it is necessary to understand the factors controlling the reservoirs deposition and distribution.

To image the distribution of subsurface reservoirs within the Songkhla Basin, several seismic attributes could be applied. The analysis of seismic attributes such as root mean square (RMS), acoustic impedance, spectral decomposition, and similarity can delineate the subtle structural and stratigraphic from the ordinary seismic amplitude data which will allow the structure and depositional environment to be interpreted (Chopra and Marfurt, 2005). The reservoir distribution, depositional environment, and their relation to the structural evolution across the syn-rift to post-rift transition could be characterized.

Although there have been more research studies about the tectonics and sedimentations in the recent years, a wide variety of questions concerning the control of tectonic on sedimentary pattern and facies distributions still remain, especially within the syn- to post-rift transition in the GOT.

### 1.3 Aims and objectives

The present work aims to examine and expand the knowledge on the relationship between structural evolution and stratigraphic sequences in the syn – post rift transition in Songkhla Basin, Gulf of Thailand (GOT).

The study area is one of the least studied and least published on the tectono-stratigraphic processes in the GOT. Since the tectonic mechanisms are changing from syn- to post-rift, the corresponding channel morphology and characters are expected to change accordingly. The

broad, main aims of this thesis are as follows:

- To investigate how faults/structures generated by tectonics control channel morphology and facies distribution, especially during the cessation of faulting activities
- To improve the knowledge of fluvial depositional system in response to tectonic control, especially during the syn- to post-rift transition.
- To use seismic attribute methods to reveal the channel size, shape and orientation in the syn- to post-rift transition period.

### 1.4 Study area

The Cenozoic N-S trending Songkhla rift basin, is located in the southwest GOT in water depths of less than 25 meters. The basin exhibits a half-graben geometry, basin with the boundary fault zone on the western side of the basin comprising a series of N-S to NNE-SSW, east-dipping normal faults.

The main study area within the Songkhla Basin is an area of 700 km<sup>2</sup> that is covered by 3D seismic reflection data (**Figure 1**). The area was chosen to better understand the tectono-stratigraphy of the syn- to post-rift transition between late Early Miocene to Middle Miocene.

**Figure 1** (a) Regional tectonic features within and around Sundaland (modified from Searle and Morley, 2011). (b) Location of Songkhla Basin in the Gulf of Thailand (blue square). (c) Songkhla concession block with the location of the 2D and 3D seismic reflection survey and Songkhla-D06, development well (modified from Morley et al., 2011).

### 1.5 Previous studies

In the Gulf of Thailand (GOT), the syn- to post-rift transition represents a gradual change from extensive fault activity to localized faulting, which is particularly complex because local structural development/tectonics is diminishing through regional subsidence. The evolution of these fault systems, including their nucleation, propagation and linkage, can be extracted from the sedimentary record. However,

within GOT, there is limited documentation regarding how channel morphology and facies distribution changes during the syn-rift to post-rift transition.

Major reservoirs in GOT are mainly fluvial sandstones deposited throughout the Miocene syn- to post-rift stages, and many of them are located in the transition from syn- (fault-controlled sedimentation) to post-rift (subsidence controlled depositional). A few research studies (Ahmad et al., 2014; Manh Do, 2013; Thi Tran, 2013; Praidee, 2013; and Inthana, 2013) have been published on mapping subsurface fluvial sandstones and detecting subtle faults in the GOT, using the seismic attributes to extract the reservoir architectures and extension.

Manh Do (2013) applied seismic attributes comprising Inversion, RMS, and Spectral decomposition to identify the depositional and architecture of the fluvial systems in the Southern Songkhla Basin. The results show that the inversion and spectral decomposition (at selected frequencies) provide better resolution of seismic imaging on channel morphology compared to the RMS in the deep, Early Miocene section. He concluded that the sedimentation in Songkhla Basin was controlled by syn-rift deformation from Oligocene to Early Miocene, while during the Middle Miocene the sedimentation was possibly controlled by the thermal subsidence due to the cessation of the main phase of rifting.

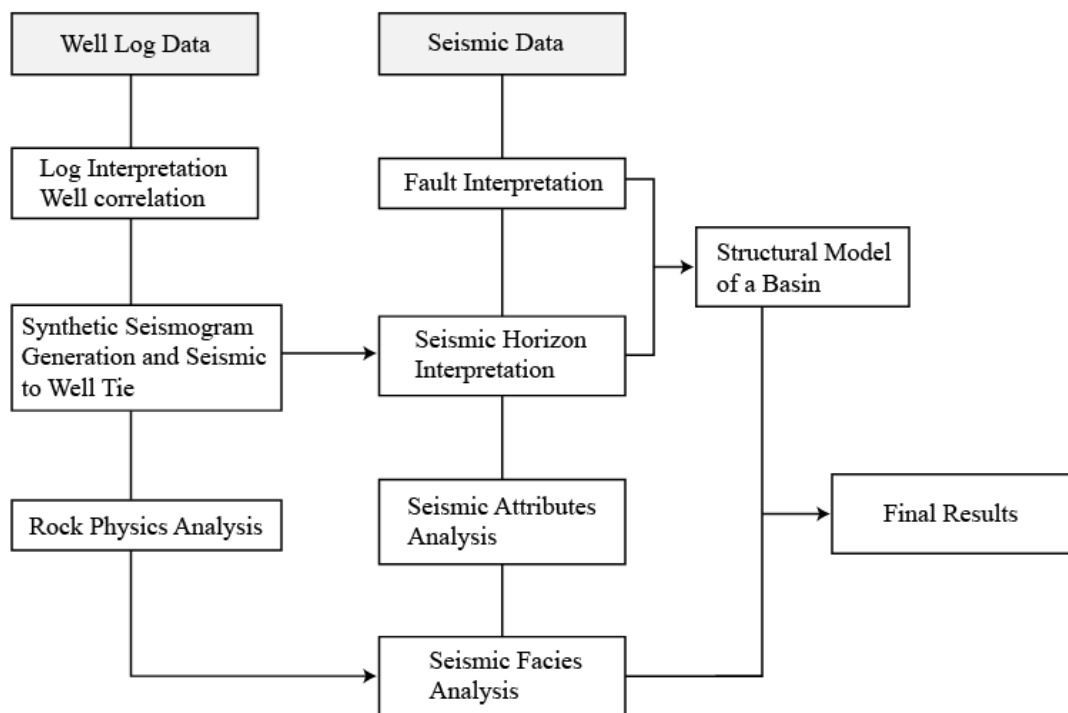

For the northern Songkhla Basin, Thi Tran (2013) concluded that the quantitative data of seismic geomorphology provided useful information for hydrocarbon reserve estimation. He also concluded that the RMS attributes provided the best seismic image of the fluvial channel morphology in the shallow part, which was well correlated with the wireline logging from the drilled wells.

Lawwongngam and Philip (1993) stated the tectonic and climate in Songkhla Basin controlled the changes of depositional environments, from lacustrine to mixed fluvial and perennial lake and transition to the low energy floodplain from Oligocene to Middle Miocene.

## CHAPTER II DATA AND METHODOLOGY

### 2.1 Introduction

The data used in this thesis comprises of 2D and 3D seismic reflection surveys, combined with borehole wireline log data, and information obtained from the industry unpublished reports, such as cuttings and sidewall core descriptions. All of these data sets were integrated and interpreted using Kingdom Suite (IHS), Petrel (Schlumberger Inc.), Traptester (Badley Geoscience Ltd.), and Hampson-Russel Suite (CGG). **Figure 2** illustrates a comprehensive workflow adopted for this research.

**Figure 2** General workflow implemented for this thesis research.

## 2.2 Data set and software

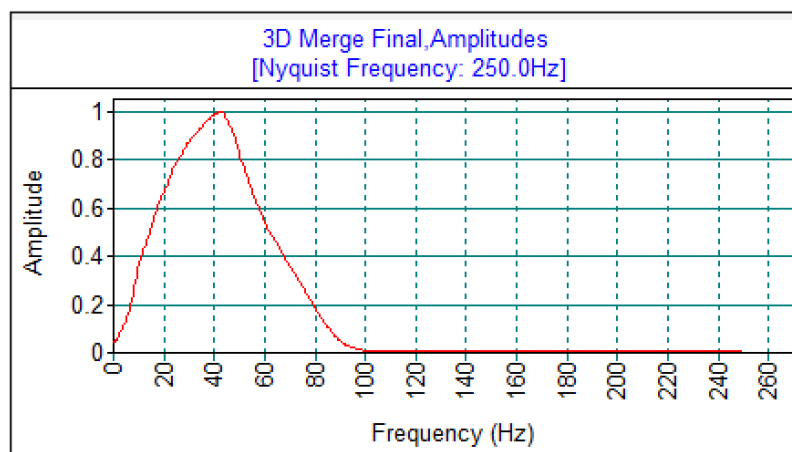

### 2.2.1 Seismic survey data

The study focuses in an area of 700 km<sup>2</sup> within Songkhla Basin, which covered by 2D and 3D seismic reflection surveys (**Figure 1; Figure 3**). The SEG-Y format, 3D time-migrated seismic reflection survey consists of 1940 inlines and 3104 crosslines, with inline spacing of 12.5 meters (m) and a sampling interval of 4 millisecond (ms). The seismic data are zero phase and normal polarity (SEG convention), where an increase in acoustic impedance is displayed as a positive amplitude (black peaks) on the seismic cross section. The maximum frequency recorded is about 100 Hz, and the dominant frequency in the interval of interest ranging is about 40 Hz (**Figure 4**).

**Figure 3** 3D and 2D Seismic surveys and well locations.

**Figure 4** Frequency spectrum of seismic data within the interval of interest, 0-2 second.

Fault interpretation and horizon mapping are based on the 3D seismic volume, supplemented by a regional 2D reflection survey that covers a large area of the Songkhla Basin. The interpretation was conducted using 20 line spacing for the 3D seismic reflection data (250 meters' grid), sub-perpendicular and sub-parallel to average fault strike, as well as arbitrary lines oblique to fault strike.

### 2.2.2 Well data

In order to investigate the tectono-stratigraphic evolution of the Songkhla Basin, a total of seven wells covering the entire study area were selected, i.e., SK1, SK2, SK3, SK4, SK5, SK6, and SK7, in order to correlate the regional and local stratigraphy with seismic data covering the study area.

**Table 1** shows all the Songkhla Basin well data being used, which comprises of final well reports, check shot, and composite logs.

Well	Gamma ray	sonic	Density	Neutron	checkshots	Bio data	Data available (meter)	
							From	Total depth (TD)
SK1	X	X	X	X	X	X	335	2005
SK2	X	X	X	X		X	335	2717
SK3	X		X	X	X	X	579	3011
SK4	X		X		X	X	1179	3188
SK5	X	X	X	X	X	X	396	2644
SK6	X	X	X	X	X	X	457	2790
SK7	X	X	X	X	X	X	1067	2816

**Table 1** Well data being used for Songkhla Basin study.

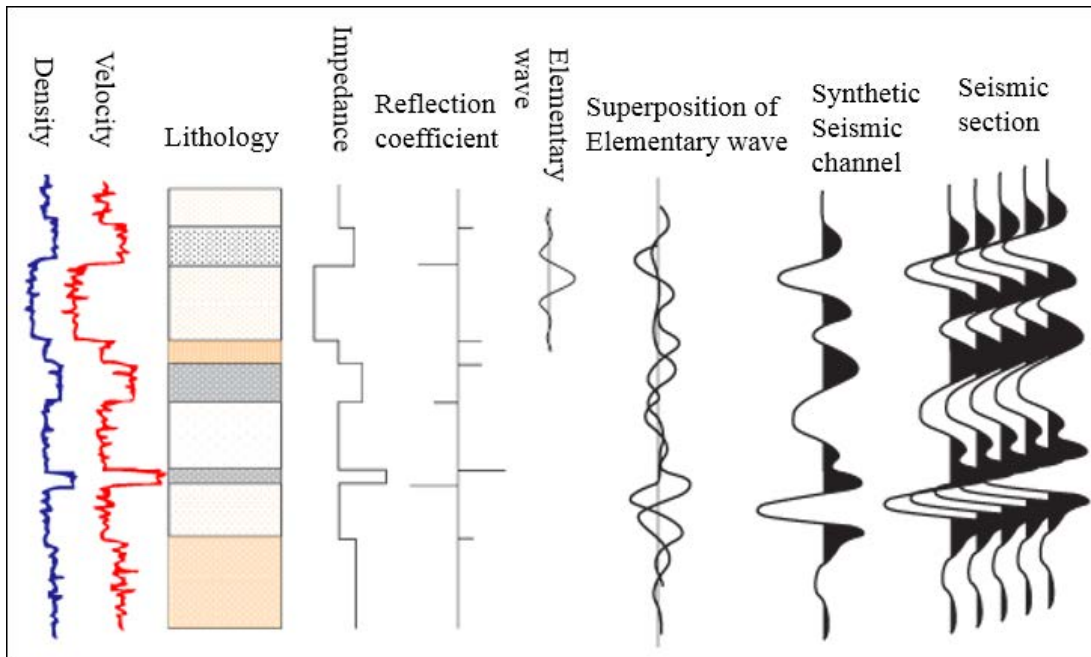

### **2.3 Approaches and methodology**

This study focuses on the application of various complementary data gathering techniques to better understand the impact of tectonics on the syn-rift to post-rift transition. An overview of the techniques used is briefly presented in this chapter. For more specific descriptions of the methodologies, the details can be found in **Chapter 3** and **Chapter 4**.

#### **2.3.1 Seismic and well correlation**

The purpose of the seismic and well correlation (seismic-well tie) is to have more accurate control on mapping subsurface stratigraphy. Synthetic seismograms are constructed to tie the well information in depth to seismic data in time (two-way time, TWT).

As shown in **Figure 5**, the acoustic impedance at the wells was calculated using the velocity data from sonic log and the density data from density log. After that, the reflection coefficients at each interface between contrasting velocities were calculated. The chosen synthetic wavelet, which has a frequency response and band width similar to the nearby seismic data is used to convolved with the reflection series for the entire well to generate the synthetic seismic trace. This synthetic trace closely approximates a trace from seismic lines that pass close to wells with the appropriate logs. The stratigraphic markers at intervals of interest can then be transferred from the well to seismic reflection data.

**Figure 5** General seismic and well correlation process (Simm and Bacon, 2014).

### 2.3.2 Throw-length profiles

The geometry and evolution of faults have been study widely using displacement-length profiles to demonstrate the variations in displacement distribution on the fault plane along strike (e.g., Gawthorpe and Leeder, 2000; Kim and Sanderson, 2004; Morley, 2014). The variations in displacement can be used to analyze fault growth, propagation, interaction, and linkage.

Fault displacement ( $D$ ) is the relative movement of two originally adjacent points on the fault surface, where displacement contours of the fault surface are ellipsoidal and bounded by zero displacement or tip line loop (**Figure 6**). Fault length is the distance between fault tips that is usually measured along the fault trace and in the horizontal plane (e.g., Scholz and Cowie, 1990; Peacock and Sanderson, 1991). For normal faults, the throw is usually obtained from well data.

The relationship between maximum displacement ( $D_{max}$ ) and maximum fault length ( $L$  or  $H$ ) is generally written as a power law relationship:

$$D_{max} = cL^n,$$

Where the value of  $c$  is a constant, related to fault displacement at unit length. The value of the exponent  $n$  ranges between 0.5 to 2.0, where for normal faults, the range of  $n$  is between 1 to 2 (Watterson, 1986, Walsh and Watterson, 1988; Marrett and Allmendinger, 1991; Dawers et al., 1993, Cartwright et al., 1995; Dawers and Anders, 1995; Kim and Anderson, 2004). In tectonic environments with the uniform properties, the relationship of the maximum displacement to the fault length is linear scaling (i.e.  $n=1$ ), making  $n$  a constant of the proportionality determined by the ratio of  $D_{max}$  to  $L$ . Many factors affect the relationship including the mechanical stratigraphy and how overlapping faults interact (for example, Cowie and Scholz 1992).

**Figure 6** (a) Schematic illustration of an ideal, isolated fault. The displacement profile indicates maximum displacement near the center. (b) The fault plane with displacement contours. Stippled lines are the hanging-wall and footwall cutoff lines and the distance between them indicates the dip separation (Fossen, 2010).

In this study, throw versus fault length along the fault plane is used to demonstrate the fault geometry and the variations in throw distribution of five major western boundary faults in order to retrieve the fault growth history and their evolution. The throw-length profiles were constructed from five major horizons covering the syn- to post-rift interval. The fault throw values were measured based on the offset reference horizons in the hanging wall and footwall in seconds (s) two-way time, perpendicular to the strike of faults.

### **2.3.3 Rock physics analysis**

Rock physics analysis is used to establish the link between seismic amplitudes and geological facies and reservoir properties based on the behaviour of seismic waves propagating through rocks. Different rock properties will directly control the stress-strain relationship and the corresponding seismic response. In a standard seismic interpretation workflow, rock physics analysis is usually used to correlate impedance and elastic parameters to specific rock properties.

P-wave velocity ( $V_p$  or primary wave), S-wave velocity ( $V_s$  or secondary wave), density ( $\rho$ ), elastic impedance (EI) and acoustic impedance (AI) were derived from well log data at well locations to determine rock properties that can be used to discriminate lithology of sands and shales. The cluster separation of these parameters on cross plots was used to identify lithological facies. If the separation of facies using AI/EI cross-plots at well log scale is poor, then such facies discrimination at the seismic scale is also likely to be poor.

#### **2.3.4 Seismic attributes analysis**

Seismic attributes analysis plays an important role in unlocking hidden information from seismic amplitude data. It has been proven that seismic attributes are very useful tools and have been successfully applied to different geological setting (clastic, carbonate, and salt related basins) as well as different tectonic setting (extension, compression, and strike slip regimes). Nowadays, seismic attributes have been increasingly used in both exploration (basin scale stratigraphy and structural) and development (reservoir scale characterization for lithofacies and flow units) as one of the workflows to help identify prospects, determining depositional environments (e.g. fluvial or deep-water channels, carbonate build-ups, salt domes), detecting and enhancing faults and fractures for the structural evolution, and even provide direct hydrocarbon indication.

Seismic attributes are the components of the seismic data, which can be derived, extracted, and computed in order to visually enhance or quantify geological features of interest that might be subtler in a traditional seismic image, leading to a better geological or geophysical interpretation of the data. It was introduced as part of the seismic interpretation in the early 1970's. Now it has been widely used for geological and geophysical interpretations. Good seismic attributes are directly sensitive to the changes in seismic impedance and allow us to define the structure and depositional environment (Chopra and Marfurt, 2005).

In this research three types of seismic attributes have been applied following Brown (1996, 2004) classification: (1) the Time/horizon attributes of coherence and Curvature; (2) the amplitude attributes of Mean amplitude, RMS (root mean square) amplitude, Maximum amplitude; and (3) the frequency attribute which is normally called spectral decomposition. The seismic attributes that provide good results in this study are listed below.

### 2.3.4.1 Similarity

Similarity (known as a Lateral Continuity Attributes) is computed as semblance that is determined by considering a user-selected number of traces. The semblance is a measurement of coherent power existing between a number of traces versus the total power of all traces, as given by:

$$Semb(z) = \frac{\sum_{\tau=-N/2}^{\tau=N/2} \left\{ \sum_{m=1}^M f_m(z + \tau) \right\}^2 - \sum_{\tau=-N/2}^{\tau=N/2} \sum_{m=1}^M f_m^2(z + \tau)}{\sum_{\tau=-N/2}^{\tau=N/2} \sum_{m=1}^M f_m^2(z + \tau)}$$

where:  $f_m(z)$  = the m'th trace of the gather;  $N$  = the length of the computational window in both time and depth domains and  $z$  = stands for either time or depth.

The number of traces depends on the signal to noise ratio (poor S/N, more traces), (more curvature, less traces), and higher lateral discontinuity resolution (better resolution, less traces) (IHS Kingdom, 2014).

It is an effective tool to determine the lateral changes along traces that might be associated with the geological features, i.e., faults and stratigraphic boundaries. In this study, the similarity volumes were generated from the full stacked seismic volume. The white colour represents the highest similarity, where black colour represents the lowest similarity (non-similarity).

**Figure 7** Comparison of similarity attributes (a) and seismic amplitude (b) on time slice 0.78 second.

#### 2.3.4.2 Root mean square (RMS)

The Root Mean Square (RMS) is a post-stack attribute, which computes the square root of the sum of squared amplitudes divided by the number of samples within the specified window being used following the equation of;

$$X_{rms} = \sqrt{\frac{(X_1^2 + X_2^2 + \dots + X_n^2)}{n}}$$

Where  $X_i$  is the seismic amplitude of the  $i^{\text{th}}$  sample,  $X_{rms}$  is the amplitude of RMS seismic attribute and  $n$  is the number of sample.

The RMS is very sensitive to changes in acoustic impedance. As a result, it emphasizes the variations in acoustic impedance in the selected window and provides information about the relative value of acoustic impedance of rocks. However, RMS is sensitive to noise as it squares every value within the window. Commonly, the higher

acoustic impedance variation, the higher RMS values will be. The high RMS in channels may cause by either high acoustic impedance contrast between channel fill with surrounding lithology or high acoustic impedance contrast between filled-sediments.

**Figure 8** The Examples of original volume (left) and resultant RMS amplitude attribute volume (right) (after OpenWorks® software).

#### 2.3.4.3 Spectral decomposition (SD)

Spectral decomposition attributes are the transformation of a seismogram (seismic signal) to a frequency domain of the seismic bandwidth, which provides a high detail for reservoir imaging and mapping of temporal bed thickness and geological discontinuities within the seismic survey by breaking down seismic signal into its' component frequencies. Many researchers have developed different methods to breakdown the seismogram to frequency for example; the conventional Fourier Transform, CWT (Continuous Wavelet Transform), MPD (Matching Pursuit Decomposition) and EPD (Exponential Pursuit Decomposition) methods for transformation of data to frequency domain. The latter two techniques offer more accurate analysis.

In this study, the conventional short window discrete Fourier Transform (SWDFT) has been applied using Kingdom Suite (IHS) software. The attribute computation algorithms have been developed by M. T. Taner and Associates at Rock Solid Images, where frequency/wavenumber decomposition splits seismic trace energy into spectral sub-bands based on Gabor-Morlet complex wavelet transform, followed by computations of the envelope of the complex trace in each sub-band (IHS Kingdom, 2014).

**Figure 9** Short Windows analysis (Quoted from Partyka et. al.,1999).

## **CHAPTER III**

### **GEOLOGICAL SETTINGS**

#### **3.1 Introduction**

The regional development of Cenozoic rift basins in Thailand is complex, with older development of basins in the eastern and southern Gulf of Thailand (GOT) (Eocene-Oligocene), and younger development (Late Oligocene to Miocene) passing northwards and westwards (Travena and Clark, 1986; Searle and Morley, 2011; Racey, 2011; Morley, 2015). In the eastern GOT, major extension ended around the Oligocene-Miocene boundary. In the western GOT, rifting continued into the Miocene, and in northern Thailand, rifting ended in the Late Miocene. Some basins, particularly in central and northern Thailand, display evidence for inversion, which occurred in several phases during the Miocene and Early Pliocene (Morley et al., 2011; Morley, 2001; Morley, 2009). Other basins show evidence for rotation of the extension direction during the Miocene, which results in relatively complex fault patterns. In addition, the influence of pre-existing fabrics on rifting has produced varying degrees of faulting oblique to the extension direction (Morley et al., 2004; Morley, 2016).

#### **3.2 Geological settings of Gulf of Thailand Cenozoic Basins**

Thailand has a complex Cenozoic geological history of deformation and sedimentation and lies within the continental core of SE Asia called Sundaland, which covers a large part of present-day Southeast Asia (i.e., Cambodia, Laos, Vietnam, Thailand, Peninsular Malaysia, most of the Sumatra and Java, part of Borneo, and all their respective continental shelves). It is surrounded by active and complex tectonic boundaries: (a) Himalayan Orogeny belts in the northwest, (b) subduction of the Indian oceanic crust in the west-southwest-south (Andaman-Sunda-Java Trench), (c) collision of Australia continental crust with eastern Indonesia in the southeast (Timor Trough), (d) a number of marginal basins opening up during Cenozoic and the South China Sea in the east (Hall & Morley, 2004; Hall, 2008). Sundaland was built from continental

fragments that were separated from Gondwana and assembled in the end of Triassic during the Indosinian Orogeny, and then it was detached later to form the southern part by the continental fragments rifted from Australia during the Cretaceous (Hall and Morley, 2004; Hall, 2011; Hall, 2012; Charusiri, 2009). It lies on the thin hot, weak continental lithosphere with considerably high geothermal gradient ranging from 3.6-8 °C/100m (2.55 °C/100 m is considered as normal geothermal gradient) and high heat flow up to 110mWm<sup>2</sup> (Pigott and Sattayarak, 1993; Morley and Westaway, 2006). It was exposed as land during the Pleistocene lowstands and contains a large number of Cenozoic sedimentary basins, which formed between the Paleogene and the Middle Miocene (Morley and Racey, 2011).

Two principle tectonic blocks can be identified in Thailand; the Indochina Block in the east and the Sibumasu Block in the west (Racey, 2011; Hall and Morley, 2004; Metcalfe, 2010). The Indochina block comprises of Eastern Thailand, Cambodia, Laos, and Vietnam, while the Sibumasu block comprises of Myanmar, Western-Northwestern Thailand, and West Malaysia (Hall and Morley, 2004) (**Figure 10**). The opening of Cenozoic basins in Thailand have been widely discussed as strike-slip pull-apart basins (Tapponnier et al., 1986; Polachan and Sattayarak, 1989) or continental extension basins (Longley, 1997; Wheeler and White, 2002; Watcharanantakul and Morley, 2000). The collision of India with Asia began in the Eocene period about the same time as the development of Cenozoic basins, therefore the deformation in Indochina and SE Asia was interpreted as a result of the India-Asia collision (Tapponnier et al., 1986; Peltzer and Tapponnier, 1986). The recognition of the major strike-slip faults such as the Three Pagoda, Mae Ping and Red River Faults running cross the Indochina, South China, and disappear offshore was interpreted to cause the opening of Thailand Cenozoic basins as pull apart basins (Tapponnier et al., 1986; Polachan and Sattayarak, 1989). Some authors projected these faults to offshore and linked to Borneo Geology (Tapponnier et al., 1986; Briais et al., 1993; Lee and Lawver, 1995). However, these interpretations have been conducted base on the regional features without detailed analysis.

Cenozoic rift basins in Thailand formed a failed rift system, and they are intracratonic rift basins located in the central part of Sundaland. They were developed

in a complex tectonic setting significantly different from the other typical continental failed rift basins, e.g., East African Rift System, Central African Rift System, and the North Sea (Travena and Clark, 1986; Searle and Morley, 2011; Racey 2011; Morley, 2015). The key differences include: (a) widespread occurrence of low-angle normal faults found onshore Thailand; (b) basin inversion alternating with rifting; (c) diachronous initiation and cessation of rifting; (d) rapid subsidence with very thick Tertiary sediments; and, (e) extensive low-displacement post-rift faults (Morley, 2015).

**Figure 10** Thailand principle structural map, including two principle tectonic blocks, Sibumasu in the west (green) and Indochina in the east (yellow) (Ridd et al., 2011).

The timing of rifting and onset of post rift subsidence is diachronous, younging from east to west in the GOT. The end of rifting is also young in Central and Northern Thailand. The basins have also undergone the episodic inversion during Miocene, indicating the fluctuation in the stress stage with time (Morley et al, 2001; Morley 2001; Morley 2009). The timing and location of inversion in Thailand is highly variable. Some basins are not influenced by any inversion, while the others display multiple events and alternating with phases of extension over a period of 15-20 Ma (Morley et al, 2001; Morley 2001; Morley 2009). Inversion was well developed in the Malay Basin, but poorly developed in the GOT, while the intensity increasing northward to Central and Northern Thailand. The Central Thailand was affected by inversion during Early to Late Miocene, while basins in Northern Thailand were inverted at different times between the Late-Oligocene to Late Miocene and the Plio-Pleistocene (Morley, 2014).

**Figure 11** Location of the Cenozoic structure and basins in Thailand (Morley et al., 2011).

### 3.3 Gulf of Thailand structural framework

The Gulf of Thailand (GOT) is a shallow sea (water depth less than 100 meters) located on the southern edge of the Eurasian Plate covering an area of 270,000 km<sup>2</sup>. It was dominated by the development of Cenozoic rift systems and post-rift basins with extensive sedimentation since the Eocene (Racey, 2011). It is divided by the north-south trending Ko Kra Ridge into two regions, east and west. The eastern GOT comprises the large Pattani, Khmer and North Malay Basins. On the other hand, the

western GOT comprises smaller, narrow, elongate basins: Western Basin, Kra Basin, and Chumphon Basin, which in turn are separated from each other by the north-south trending basement horsts (Racey, 2011) (**Figure 11**, **Figure 12**). The two major hydrocarbon producing basins are Pattani and North Malay Basins.

**Figure 12** Regional tectonic map of western Southeast Asia modified from Packham (1996) and Leloup et al. (1995). The rift basins of Thailand are in dark grey. Cross-section through the northern Gulf of Thailand is from Oudom-Ugsorn et al. (1986). Strike-slip model for the Tertiary basin formation in the Gulf of Thailand is after Polchan and Sattayarak (1989) (after Morley et al. 2011).

The Cenozoic rift basins are extensively present in the Gulf of Thailand, and extend onshore into the central and the most northern parts of the country. They are a string of north-south trending basins filled by the continental deposits, predominantly of half graben geometry (Morley et al. 2011; **Figure 13**). 3D seismic reflection data

shows significant changes in syn-rift structural style of extensional faults between the half graben and the synformal geometries. Synformal geometry with low displacement on wedge shape boundary faults is found in the north and central part of Pattani Basin, while typical half graben geometries are well defined in south Pattani basin, the western GOT and North Malay Basin (northern part of Malay Basin). Watcharanantakul and Morley (2000) stated that the synformal geometry in the north and central part of Pattani, and the half graben bounded by east dipping boundary faults of the East Kra and Kra basins are compatible with a ramp-flat extensional detachment geometry.

**Figure 13** Cross-section through the Gulf of Thailand is from west – east showing half graben geometry of rift basins (after Morley et al. 2011).

Determining the location of syn to post rift transition in the eastern GOT, especially northern half of the Pattani basin, from the seismic reflection data is challenging for the synformal geometry basin. This is due to the thick post-rift sequences (leading to poor imaging seismic data on the syn-rift section) and the presence of numerous low-displacement conjugate normal fault sets. These conjugate fault systems were developed during the post rift subsidence with complex transferred zones or locally known as graben shift, where the opposite-dipping fault tips slightly overlap (Morley, 2015). The complex transfer zones are caused by the change in dip domain between fault sets propagating along the strike direction. Many of them are influenced by the pre-existing fabrics leading to the more oblique NE-SW and NW-SE trends (**Figure 12**). In contrast, in the southern part where the typical half graben

geometry is well developed, the location of the syn to post rift can be easily identified as the deepest depocenter is located near the major boundary faults (Kornsawan and Morley, 2002; Watcharanantakul and Morley, 2000; Morley and Westaway, 2006; Morley et al., 2011).

The Pattani and Malay Basins experienced considerably rapid post-rift subsidence during the Early – Mid-Miocene with up to 6-8 km of Miocene – Recent post rift section. The rapid subsidence rate contributed to thicker sediment succession if compared to the classic post-rift sequences such as the North Sea, East African Rift, and Anza Graben (Morley, 2015). Identifying the cause of rapid subsidence is complicated and cannot be explained by a simple subsidence mechanism. Besides the high subsidence rate, the basins have high heat flow (up to 110mWm<sup>2</sup>) and high geothermal gradient (up to 6 C/100 m) making it different from the other continental, failed rift basins (Morley and Westaway, 2006). The only comparison of high subsidence rate is the strike-slip pull-apart basins. However, the offshore seismic reflection data shows that the post-rift subsidence section formed as a synformal shape in broad area and was not controlled by any large-displacement faults (Morley and Westaway, 2006). Hence, the proposed pull-apart setting as the cause of thick sediments (Tapponnier et al., 1986) is not applicable in these basins. Instead Morley and Westaway (2006) proposed the rapid subsidence in the GOT was caused by the lower-crustal flow driven by sediment loading during the post-rift stage.

### **3.4 Stratigraphy of Thailand offshore basins**

#### **3.4.1 Kra and Western basins**

Rifting was initiated in the Kra and Western Basins in the Late Oligocene (Praditnan and Dook, 1992). Two Tertiary stratigraphic units were identified in the Kra and Western Basins by Praditnan & Dook (1992): 1) post-rift Late Miocene – Recent Chao Phraya group; 2) Late Oligocene-Middle Miocene syn-rift section. Both units are separated by the Mid Miocene Unconformity (MMU) and are different from the Pattani Basin. The syn-rift section was divided into 2 groups, Kra A and Kra B, while the post-rift was defined as Kra C. Kra A and Kra B are dominated by alluvial and lacustrine

sediments, while Kra C is interpreted as alluvial sediments associated with braided and meandering river deposits, comprises of reddish-brown to grey claystone with sandstone and minor limestone (Morley and Racey, 2011). For the Western Basin, the syn-rift section is dominated by floodplain deposits, with poorer development of lacustrine sediments. The syn-rift section stratigraphy is divided into three units, i.e., WA, WB, and WC. WA, the oldest unit, composed of alluvial fan deposit and some lacustrine episodes marked by the several hundred meters of limestone with thin claystone (Morley and Racey, 2011). The WB unit is dominated by low energy fluvial floodplain environment red silty clays and calcareous mudstones with thin limestones. The WC unit contains coarse, pebbly sandstones and a high percentage of sand. WC is interpreted as high energy fluvial floodplain that is different from the WB unit (Morley and Racey, 2011). The Chao Praya Group shows an influence of marine conditions, and ranges between estuarine, intertidal, and shallow marine (Morley and Racey, 2011; **Figure 14**).

**Figure 14** The western Gulf of Thailand (after Morley and Racey 2011).

### 3.4.2 Chumphon basin

Chumphon Basin stratigraphy was divided into three units: Unit I, Unit II and Unit III (Pradidtan, 1989; Heward et al., 2000). Unit I was deposited in the syn-rift sequence (probably of Late Eocene-Oligocene) comprises predominantly of alluvial plain and transgressive marine clays and shales with interbedded medium to coarse grain fluvial sands. Unit II was deposited in the Miocene syn-rift. It was divided into two groups: Unit IIa and Unit IIb. Unit IIa is the Lower Miocene age, overlying the erosional half graben of Unit I comprising of grey to dark grey shales and siltstones

with Minor sandstone and lignite. While Unit IIb was deposited in the Middle Miocene comprises of claystones and fine to coarse grain sandstones deposited in an alluvial floodplain environment (Morley and Racey 2011).

### **3.4.3 Nakorn basins**

Songkhla and Nakorn Basins appear to have a long rift history similar to Chumphon Basin. There is little published stratigraphy for the Nakorn Basin.

### **3.4.4 Pattani basin**

The Pattani and North Malay Basin-fill is predominantly fluvial-lacustrine facies from Oligocene to Mid-Miocene before becoming more marine or Marginal marine clastic-dominated facies in the Late-Miocene to Recent. Lockheart et al. (1997) published the stratigraphic sequences in the southern Pattani, while the central Pattani Basin stratigraphy is from Jardine (1997). Five stratigraphic sequences have been identified in the Pattani Basin; Sequence I, II, III, IV, and V. Morley and Racey (2011) provided the additional information to the Pattani stratigraphic descriptions based on the better seismic images from well-developed sections. From oldest to youngest, the five stratigraphic sequences are:

- Sequence I sediments were deposited in the syn-rift section comprises of a mixture of the proximal alluvial fan/alluvial plain and lacustrine sediments in the Late Eocene to Oligocene, plus the Late Oligocene to Early Miocene post-rift lacustrine shale unit in the upper part of the unit. This sequence is the important petroleum source rocks, which contains organic matters both algal and terrestrial plant materials. The top of the sequence 1 is bounded by the Mid-Tertiary Unconformity (MTU), regional unconformity.
- Sequence II was deposited during Early-Middle Miocene comprises fluvial floodplain and delta plain and intertidal deposits overlying the MTU. Seismic data shows Sequence II onlaps Sequence I and is conformably overlain by Sequence III. This sequence is the potential source-reservoir interval.

- Sequence III was deposited during the Middle Miocene. The sediment depositional environments are marginal marine to lagoonal delta plain. The sequence comprises sand and grey shales with some coals and carbonaceous shales. This sequence is believed to be the main source rocks in the Pattani and North Malay basins.
- Sequence IV or the Upper Red-beds was deposited during the Late Middle - Late Miocene. The sediments are fluvial red beds. This sequence is the major reservoir in the Pattani basin. The top of this sequence is the Mid-Miocene Unconformity (MMU).
- Sequence V was deposited above the MMU during the Upper Miocene to recent. It consists of delta plain to marine sediments.

**Figure 15** Stratigraphy comparison of the major Tertiary basin in the Gulf of Thailand (Morley and Racey 2011).

### 3.5 Geology of Songkhla Basin

The N-S trending Songkhla Basin is situated in the southwestern GOT, separated from the eastern GOT by the north-south trending Ko Kra Ridge (**Figure 1 (a)**). The basin has a half graben geometry, and is controlled by a set of large-scale, N-S to NNE-SSW, east-dipping normal faults that form the basin boundary fault system along the western margin (**Figure 16**). The basin is filled by up to 4 km (approximately 2.5 seconds) of Eocene to Middle-Late Miocene continental sequences (**Figure 17**).

The syn-rift strata in the study area comprises five stratigraphic sequences (**Figure 17**). The lowest sequence is the Eocene syn-rift package, represented by discontinuous weak to bright amplitude reflectors, well data indicates this sequence is dominated by mixed lacustrine shales and fluvial-alluvial sandstones (Morley and Racey, 2011; Kaewkor et al., 2015; Rivas et al., 2016). The overlying Lower Oligocene package is characterized by continuous high-amplitude reflectors across the basin. The well data indicates the Oligocene section is dominated by lacustrine deposits comprising organic rich shales (potential source rock) together with a few sandstones. The medium to high amplitude continuous reflectors observed in the 3D seismic data from Upper Oligocene to Early Miocene represent a basin that is dominated by lacustrine shale. The Middle to Late Miocene is characterized by low-amplitude discontinuous reflectors, and well data indicates a change to dominantly fluvial, sand-prone deposits.

The uppermost package of Pliocene age is represented by high amplitude continuous strong reflectors intercalated with discontinuous weak to bright amplitude reflectors and well data indicates the depositional systems during the Pliocene were predominantly in delta plain, marginal marine and shallow marine environments (**Figure 17**).

**Figure 16** Interpreted full-stack seismic cross sections, in the east–west direction, of the Songkhla Basin showing the five major stratigraphic horizons, structural elements and lateral amplitude variations. (a) A-A' seismic cross section in

the northern part of a basin. (b) B-B' seismic cross section in the central part of a basin. (c) C-C' seismic cross section in the southern part of a basin.

Kaewkor et al. (2015) interpreted three main structural stages in the basin development: the initial syn-rift stage during the Eocene exhibits numerous low-displacement extensional faults; the second stage marks a switch to a half graben style, where many of the early domino faults became inactive; and the boundary fault becomes the dominant fault (Eocene-Lower Miocene). The final stage is post-rift subsidence that includes a phase of mild inversion during the Middle Miocene.

**Figure 17** Stratigraphy in Songkhla Basin.

## CHAPTER IV

### EVOLUTION OF A MAJOR EXTENSION BOUNDARY FAULT SYSTEMS IN SONGKHLA BASIN

#### 4.1 Introduction

In a rift basin, the deposition and distribution of the reservoirs are significantly influenced by the paleo-topography, which is largely controlled by the interaction and linkage of normal faults throughout the structural evolution. To understand the impact of structural elements towards the sedimentary successions, it is necessary to establish the basin structural evolution. Songkhla Basin 2D and 3D seismic reflection data calibrated by well data have been used to investigate the development of the boundary fault systems, including the deformation history, fault patterns, fault linkage history, and fault displacement patterns.

The main parts of this study have been published in the Journal of Asian Earth Sciences, Volume 130, 15 November 2016, Pages 239-255, under the title *“Evolution of a major extensional boundary fault system during multi-phase rifting in the Songkhla Basin, Gulf of Thailand”*.

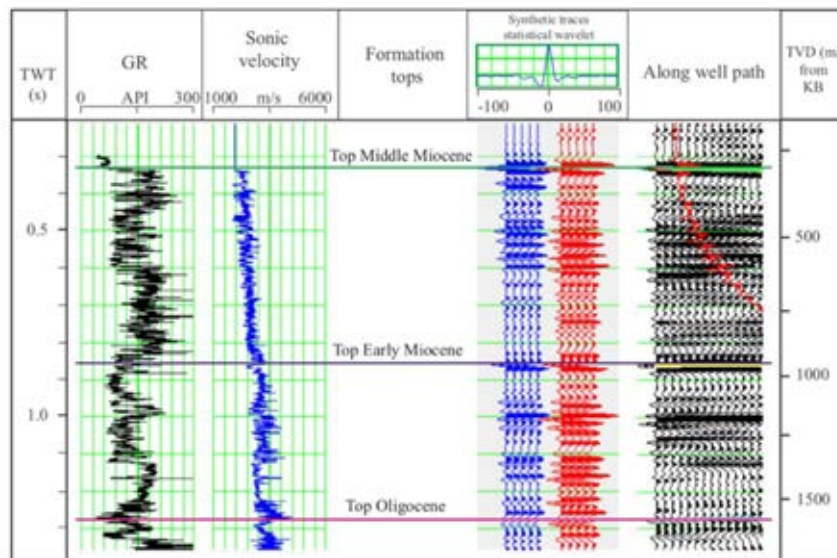

#### 4.2 Methodology

This study focuses on an area of 700 km<sup>2</sup> within the Songkhla Basin, which is covered both by 2D and 3D time-migrated seismic reflection surveys (**Figure 1 (c)**). The seismic data is zero phase and normal polarity (SEG convention), where an increase in acoustic impedance is displayed as black peaks in the seismic cross section.

The seismic profiles are calibrated with synthetic seismograms generated from five wells (Songkhla-1, Songkhla South-1, Songkhla Southwest-1, C04, and D06). This calibration ties well information in depth to seismic data in time. The synthetic seismograms show good to fair correlation. D06 is an example of a good well-tie (**Figure 18**). In order to convert time to depth, a representative time-depth relationship

was used. The time-depth relationship was derived from synthetic seismograms, which were calibrated with check shot data where applicable. Five major marker horizons on seismic correspond with flooding surfaces in the wells. Key mapped horizons are: Top Middle Miocene, Top Early Miocene, Top Oligocene, Lower Oligocene, and Base Eocene (base syn-rift) (**Figure 16**; **Figure 17**).

The faults and key horizons were interpreted based on both 2D and 3D time-migrated seismic reflection surveys (**Figure 1 (c)**; **Figure 3**). The 3D seismic survey has a line spacing of 12.5 m for both the inlines and crosslines. A 250 m grid spacing was determined to be sufficient to study the east-dipping boundary faults (20 line spacing). 2D reflection surveys that cross, and extends further west than the 3D seismic data were used to determine the boundary fault zone geometry. The seismic data is of good quality and seismic inversion results provided excellent seismic features for stratigraphy analysis.

**Fig. 4.** Correlation of D06 well logs, 3D seismic profile along well path and the constructed synthetic seismogram used to generate a synthetic trace in the study area (wellbore location is shown in **Figs. 1 and 5**). The red seismic trace is a trace around the wellbore. The blue traces are synthetic traces calculated using sonic and density logs and the statistical wavelet from seismic profile. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

**Figure 18** Correlation of D06 well logs, 3D seismic profile along well path and the constructed synthetic seismogram used to generate a synthetic trace in the study area (wellbore location is shown in **Figure 1** and **Figure 19**). The red seismic trace is a trace around the wellbore. The blue traces are synthetic

traces calculated using sonic and density logs and the statistical wavelet from seismic profile. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The consistence dip attribute calculates dip between adjacent seismic traces in a 3D seismic volume and iteratively checks for continuity of traces. Where discontinuities in the data are encountered, they are marked with a quality attribute. Hence discontinuities such as faults are highlighted in a consistence attribute volume. **Figure 19** shows the structural contrast in the north and south areas from four selected horizons extracted from the consistence dip cube. The consistence dip attribute most clearly identifies low-displacement faults.

Structural maps and throw-length profiles were used for the structural interpretation and for determining fault growth history. Fault and horizon surfaces were imported into Badley Geosciences Ltd Trap Tester software, and were used to generate fault surfaces with throw contours plotted on them. Throw-length profiles of the major boundary faults are another way to demonstrate the variations in throw distribution on the fault plane along strike. The variations in throw can be used to make inferences about fault growth, propagation, interaction, and linkage. In this study, throw measurements are displayed in two-way time (TWT). The fault throw values were measured based on the offset reference horizons at the hanging wall and footwall in seconds (s). The deepest stratigraphic unit that shows expansion of section into the hanging wall of the fault indicates the initiation age of the fault.

Changes in the amount of accommodation space and the location of sedimentary input points throughout the development of normal faults will control the distribution and the architecture of the sedimentary strata. Therefore, the thickness variation of the strata across faults as a function of the sedimentary records on the hanging-wall of a fault plane can be used indirectly to identify tectonic history of segmented fault systems (e.g. Prosser, 1993; Morley, 1999; Young et al., 2001; Henstra et al., 2015). Isochron and isopach maps are typically used to demonstrate the variations of the sedimentary thickness associated with fault development. As shown in **Figure 16** and **Figure 17**, a total of five horizons have been mapped based on the ages of the reflectors from

Eocene-Miocene, which are tied to the exploration wells in the study area. Since these seismic horizons were used for basin structural description and fault throw analysis, detailed interpretation of the horizons around the footwalls and hanging walls was carried out. Isochron maps of four stratigraphic intervals have been generated to observe the stratigraphic thickness variation around the boundary faults (**Figure 20**).

**Figure 19** Structural maps and location of five wells on the consistence dip attribute of the four major mapped horizons showing: soft linkage via relay ramps between F1-F2 and F4-F5 are shown on the (a) Base Eocene and (b) Lower Oligocene structural maps; hard linkage at breached relay ramps of F2-F3 are shown for the (c) Top Oligocene and the (d) Top Early Miocene structural maps.

**Figure 20** Isochron maps illustrate the vertical thickness changes for four intervals and the changing depocentre location from Eocene to Miocene times. (a) Base Eocene- Lower Oligocene isochron map shows the main depocenter of a basin is located adjacent to the major boundary faults. In (b) Lower Oligocene-Top Oligocene isochron map, (c) Top Oligocene-Top Early-Miocene isochron map and (d) Top Early Miocene-Top Middle Miocene isochron map, the depocentre shifts progressively towards the middle of the basin with time.

### 4.3 Fault Geometry and throw patterns

A series of normal faults, which form segments of the half graben bounding fault, are developed on the western basin margin. They dip eastwards and strike N-S to NNE-SSW (**Figure 16**). The boundary fault zone is predominantly extensional, but underwent weak inversion after extension ceased, in the Middle Miocene (Morley and Racey, 2011; Kaewkor et al., 2015). The major boundary fault segments are slightly listric in profile, and are steeper toward the northern part of Songkhla Basin. The highest observed throws occur at the Eocene horizon (base syn-rift) (**Figure 16**). There is syn-sedimentary thickening of the Eocene-Early Miocene sequences towards the bounding faults, and early-stage tilted fault blocks that affect the Eocene section (**Figure 16**; **Figure 17**). Smaller tilted synthetic faults are developed in the middle part of the basin.

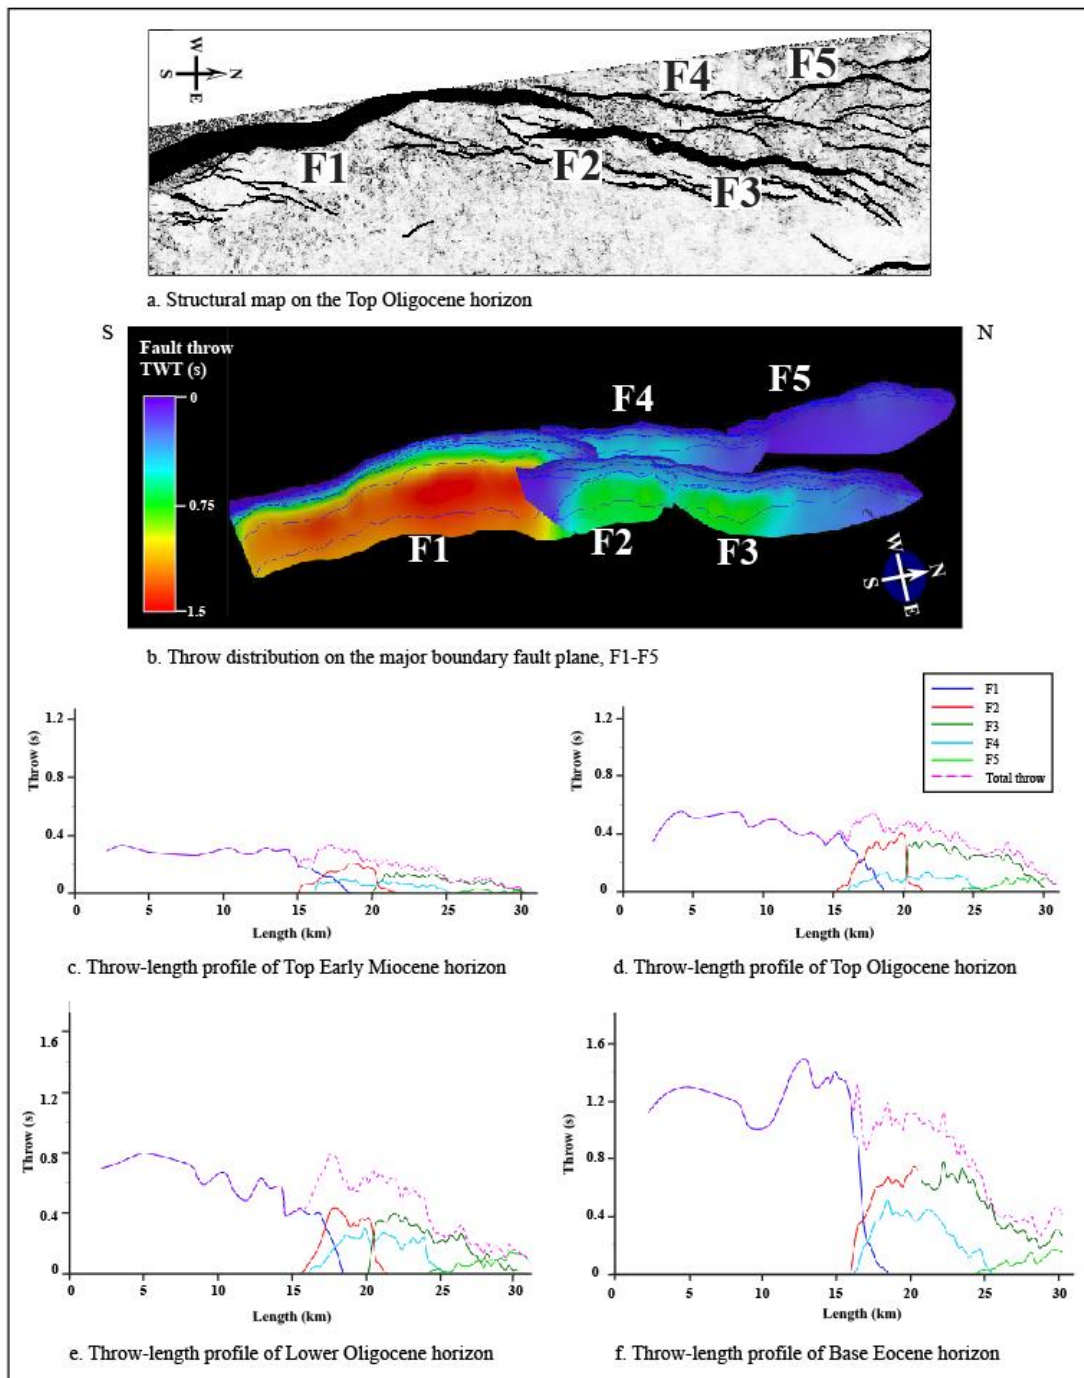

The faults forming the major syn-sedimentary boundary fault zone (F1 to F5) in the study area were chosen for detailed analysis due to their coverage by 3D seismic data (**Figure 19** and **Figure 20**). These faults tend to converge downwards either within the lower part of the Cenozoic section or possibly in the pre-Cenozoic section (**Figure 16**), but commonly exhibit soft-linked geometries, in particular relay ramp structures, in the horizons mapped in this study (**Figure 19 (b)** and **(c)**). The east dipping, N-S trending F1 is the largest fault in the study area (**Figure 19** and **Figure 20**). It is located in the south and dominates the southern half of the basin. The southern tip of this fault lies outside of the study area, within the study area it is 19 km long. F1 is slightly listric in profile. The northern part of F1 overlaps via relay ramps with F4 in the west, and F2

in the east (**Figure 19**). Expansion of section towards F1 is clearest for the Base Eocene-Lower Oligocene and Lower Oligocene-Top Oligocene intervals (**Figure 16**). The Top Oligocene-Top Early Miocene section expands towards F1, but then starts to thin towards the boundary fault within about 5 km from the fault. This thinning towards the boundary fault is strongest in the Early Miocene interval. The thinning can in part be related to Miocene inversion, and in part to the post-rift subsidence depocentre shifting to a position eastwards of the earlier fault-controlled depocenter.

As shown in **Figure 21** and **Figure 22**, the throw-length plots for F1 show that the Eocene horizon (base syn-rift) has the highest throw, which is relatively uniform (about 1.2-1.5 s) for approximately 16 km of its length. Then, in the northern 3 km, the fault rapidly loses throw to zero. Throw is less in higher horizons, and for the Top Early Miocene maximum throw is around ~0.2 s.

The throw lost by F1 to the north passes predominately onto F2/F3 and F4 (**Figure 21** and **Figure 22**). F2/F3 are connected via a breached relay ramp (**Figure 19**). Their throw patterns for the Oligocene-Eocene intervals indicate that the throw decrease on segments F2 and F3 towards the linkage point but do not die out, whereas for the Top Early Miocene horizon, the throw goes to zero approaching the linkage point (**Figure 21**). In the overlap zone with F1, the throw at the Eocene horizon level decreases from around ~1 s to zero over 3 km. F4 displays a slightly asymmetric throw profile, with the throw dying out more rapidly towards the south, than towards the north (**Figure 22 (d)**). In about 2.5 km of overlap between F4 and F1, the throw at the Eocene horizon level for F4 decreases from around ~0.5 s TWT to zero.

As shown in **Figure 22 (e)**, F5 shows a gradual increase in throw towards the north, and there are four peaks in throw along the Eocene horizon, which suggests the fault probably was linked from four earlier faults that were initially separated in the Eocene. The throw is low compared with the other faults forming the boundary fault zone. For the Top Early Miocene horizon, the throw is very low.

**Figure 21** (a) Fault polygons for F1-F5 on the Top Oligocene horizon time structural map. (b) Three-dimensional view of the major boundary fault surface with the throw distribution on the fault planes. (c)–(f) Throw-length profiles of faults F1-F5 for four horizons from Eocene to Miocene.

**Figure 22** (a)–(e) Throw distribution on the fault surface, view towards the fault surface, and the throw-length profiles of F1-F5 showing variations in throw from the southern to northern tips.

## 4.4 Discussion

### 4.4.1 Songkhla Fault Model

Relatively large faults, whose growth can be measured from variations in sediment thickness (i.e. with displacements of 10's to 1000's of metres), have been shown in many studies to display a variety of displacement and linkage patterns (e.g. Walsh and Watterson, 1988; Cartwright et al., 1996; Morley, 1999; Morley, 2016; Mansfield and Cartwright, 2001; Walsh et al., 2002; Childs et al., 2003). The simplest model for fault growth is the isolated model, where with increasing displacement, the fault undergoes symmetric lateral propagation growth (e.g. Walsh and Watterson, 1988; Cartwright et al., 1996; Morley, 1999; Mansfield and Cartwright, 2001; Childs et al., 2003). There is a close relationship between fault displacement and fault length in the isolated model, where an increase in displacement is accompanied by a proportional increase in fault length (**Figure 23 (a)**). Commonly the ratio of the fault length to displacement ranges between 10:1 to 20:1 (e.g. Scholz and Cowie, 1990; Marrett and Allmendinger, 1991; Walsh and Watterson, 1991; Needham et al., 1996).

Another common pattern occurs when after linkage of several faults, and the displacement fails to relocate to the middle of the newly created fault zone. This can occur because the sites of linkage remain relatively strong regions and inhibit slip propagation into the linkage zones (e.g. Cartwright et al., 1996; Morley, 1999; **Figure 23 (b)**). When faults link, there is an abrupt jump in fault length, causing a decrease in the fault length to displacement ratio. The linkage development that most closely follows the isolated fault model occurs when two or more faults join and the displacement value for the newly joined fault is relatively low. Then as displacement builds, the lateral propagation of the fault is stalled. Upon the displacement value approaching typical length-displacement ratios for isolated faults, lateral fault propagation is likely to resume. Generally, faults are likely to develop through a number

of cycles of linkage until reaching their final length. In the isolated fault model, faults behave independently so where two faults overlap, and their displacement values are summed, displacement may decrease in the region of overlap. This displacement deficit is a characteristic of isolated fault arrays (Walsh et al., 2002).

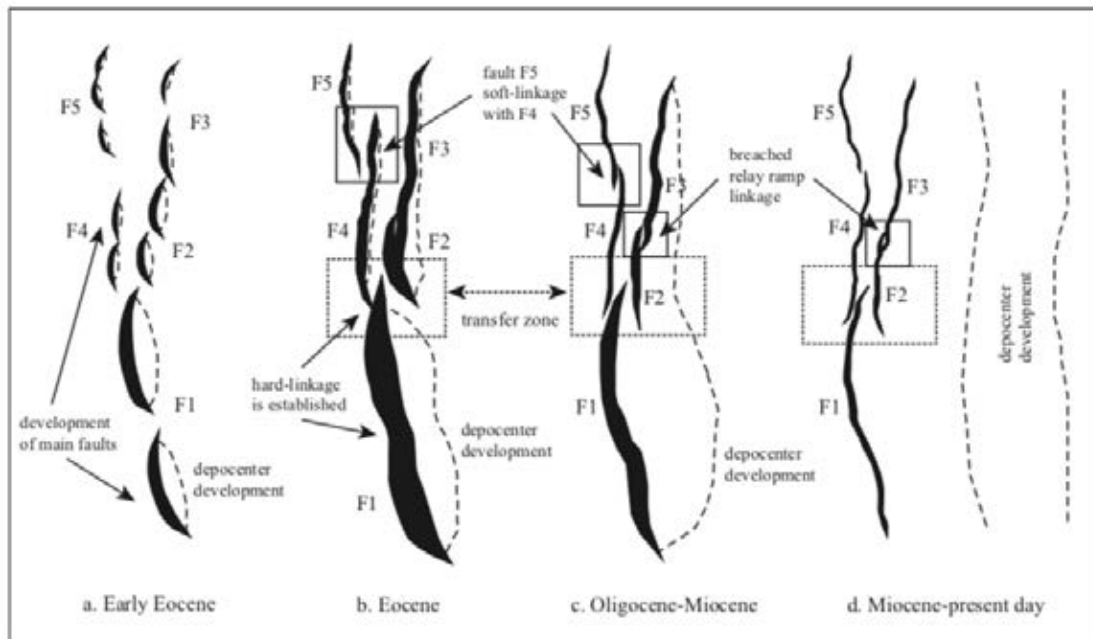

As an alternative to the isolated fault model, a fault can approach its final length very early in its displacement history (constant length model) when linkage occurs on many small faults, hence typically little syn-kinematic sedimentary record is preserved (**Figure 23 (c)**). Then, most of the fault displacement is built after the fault length has been established (Morley, 1999; Walsh et al., 2002). Consequently, during much of the life of the fault it is relatively under-displaced with respect to length. Jackson et al. (2016) concluded that the constant length model is a common feature of large extensional faults. This type of development is part of the coherent fault model (Walsh et al., 2002). The coherent fault model typically displays low, or no displacement deficits in the areas of overlapping faults (Walsh et al., 2002).

**Figure 23** Schematic illustration of how fault systems may develop in relationship with the development of the fault displacement and fault length. (a) Isolated fault model. (b) Isolated fault model with lateral propagation. (c) Coherent fault model with early linkage (following Morley, 2016).

The Songkhla Basin bounding fault zone has remained segmented throughout its throw history with the four largest fault segments (F1, F2/F3, F4 and F5) plus other minor faults showing soft linkage geometries from the Oligocene to the Miocene horizons (**Figure 19**). The fault zone has been at least episodically active for around 25-30 My. At the level of the Base Eocene horizon, F1, F2/F3 and F4 are hard linked while F5 is soft linked (**Figure 19 (d)**). F1 shows strong asymmetry of throw-length plots into the transfer zone between F1, F2 and F4, with throw decreasing more rapidly with distance in the overlap zone to the north, compared with the loss of throw to the south (**Figure 21**). Throw patterns for the Eocene horizon show total throw across the five faults decreases towards the north, and they behave as a single fault (i.e. the throw pattern followed a coherent fault model, **Figure 23 (c)**). In the Songkhla Basin, the boundary fault system is a complex zone whose throw characteristics for the Eocene suggest rapid fault growth and linkage during the Eocene from numerous segments (**Figure 24 (a)**). During the later part of the Eocene, although many of the faults became hard linked, some soft linked segments remained, but overall the throw along these faults followed the coherent model.

For the Oligocene-Miocene horizons at around the 15-20 km and to lesser degree at the 22-26 km regions of fault length along strike (**Figure 21 (d)** and **(e)**) there is a decrease in throw indicating that when the fault was reactivated later in its history the throw patterns started to switch to an isolated fault model (**Figure 23 (b)**). Extension was accommodated on the existing faults without forcing further propagation and linkage. Probably this reflects the effects of lower strain rates during the waning stages of extensional activity in the region.

**Figure 24** Schematic illustration of the evolution of major boundary faults in Songkhla Basin. (a) The small fault segments developed and propagated during the early rifting stage in the Early Eocene. (b) Fault segments propagated and hard linked to form larger boundary faults (F1-F5) in the Eocene, except F5 and F4 and F2 and F1 show soft linkage. (c) The boundary faults continue to grow by accumulating displacement with minimal lateral propagation due to the relatively low extensional activity during the Oligocene-Miocene. (d) Fault pattern near the top of the fault system, where extensional activity was low. Extension ended in the Early Middle Miocene. Dashed line indicates extent of main depocentre.

#### 4.4.2 Structural Controls on Sedimentation in Songkhla Rift Basin

The timing and degree of fault interaction and linkage exert significant impact on syn-rift stratigraphy as it controls the sedimentary input sites, types and distribution of sediment transported to a basin throughout rift basin evolution (e.g. Cowie et al., 2006). When an extensional basin is initiated, small isolated depressions are developed (e.g. Cowie et al., 2000). These depressions with relatively little accommodation space are typically initially dominated by predominantly coarse, immature, continental

deposits and marginal marine deposits (e.g. Lambiase and Bosworth, 1995; Gawthorpe and Leeder, 2000; Jackson, 2008), although they can transition upwards into more argillaceous- dominated sequences in a relatively short stratigraphic interval (< 100 m).

The throw-length analysis indicates most of the major boundary faults in Songkhla Basin have early linkage. The early linkage of the F1 boundary fault controlled the size and geometries of the main depocenter, especially during the Eocene – Oligocene. At this early stage of linkage, where faults are relatively short (< 15 km), modern geomorphology studies from the Basin and Range suggest that the majority of fluvial systems run down relay ramps parallel to fault strike, but the relationship seems to break down for longer fault lengths (Hopkins and Dawers, 2017). Greater accommodation space was created when isolated faults coalesced. Based on the stratigraphic interpretation of Songkhla Basin exploration wells, the depositional environment was mainly alluvial and fluvial. Once faults began to link, the drainage systems coming in from the hangingwall margin would have started to be re-arranged as a result of increased displacement, footwall uplift and hangingwall subsidence. This marks the time when the depositional environment in the hangingwall evolved from alluvial and fluvial environments to a lacustrine one. The way drainage adapts to changing boundary fault morphology depends on diverse factors such as fault spacing, orientation, segmentation and footwall lithology (Leeder and Jackson, 1993; Gawthorpe and Hurst, 1993; Duffy et al., 2015). The tectonostratigraphic development during this time of transition towards the establishment of a major boundary fault is generally complex compared to the rift climax as discussed by Jackson et al. (2006).

Regionally, the Cenozoic rift basins in Thailand display very different characteristics (see reviews in Morley et al., 2001; Morley 2015, 2016; Sautter et al., 2017): in northern Thailand, there was alternation of inversion with extension during the Miocene at least on three separate times, before strike-slip deformation becomes dominant in the Plio- Pleistocene). In central Thailand, there is evidence for rotation of the extension direction from E-W to NE-SW during the Miocene, as well as episodic inversion. In the Andaman Sea, rifting evolves from E-W extension to NNW-SSE transtension with time. While in the southern and eastern part of GOT, rifting begins in the Eocene and ends in the Oligocene- Miocene boundary. The rifting timing is earlier

than in the northern GOT and onshore areas. In the Andaman Sea, there is also northwards younging of the onset of rifting. There is also considerable influence of pre-existing fabrics on fault and basin morphology (Morley et al., 2004). Given this great diversity of behavior, the structural style and development of each sedimentary basin needs to be evaluated to understand the distribution of possible causes of these different effects.

The development of the Songkhla Basin is relatively straightforward in comparison with some rift basins in Thailand. However, in building the regional picture, this is significant information, and can serve as a near end member example (relatively simple extensional history), when comparing the behavior of different boundary fault zones within the rift system.

## CHAPTER V

### QUANTITATIVE INTERPRETATION OF SEISMIC ATTRIBUTES FOR RESERVOIR CHARACTERIZATION

#### 5.1 Introduction

Fluvial reservoirs are the major hydrocarbon reservoirs in the GOT, which were deposited throughout the syn-rift and post-rift periods, ranging from Oligocene to Miocene sequences. In general, the sands deposited in fluvial depositional systems have complex lateral and vertical geometries and distributions as they contain a series of point bars, overbank deposits, and sand- or mud-filled abandonment channels (Ahmad and Rowell, 2014; Jardine, E., 1997; Lockheart et al., 1997). Regarding this complexity, it is necessary to understand the factors controlling the reservoirs deposition and distribution.

To image the distributions of subsurface reservoirs within the Songkhla Basin, several seismic attributes have been applied in this study. The analysis of seismic attributes such as root mean square (RMS), acoustic impedance, spectral decomposition, and similarity can delineate the subtle structural and stratigraphic from the ordinary seismic amplitude data allow us to define the structure and depositional environment (Chopra and Marfurt, 2005). The purposes of this study are to determining the reservoir distribution, depositional environment, and their relation to the structural evolution.

The main parts of this study have been accepted for publication by the Marine and Petroleum Geology Journal under the title “*Quantitative interpretation of seismic attributes for reservoir characterization of Early-Middle Miocene syn- and post-rift successions (Songkhla Basin, Gulf of Thailand)*”.

## 5.2 Seismic database and methodology

The SEG-Y format 3D time-migrated seismic reflection survey consists of 1940 inlines and 3104 crosslines, with inline spacing of 12.5 meters (m) and crossline spacing of 12.5 meters covering a total area of 700 km<sup>2</sup> within the Songkhla basin. The seismic data are zero phase and normal polarity (SEG convention), where an increase in acoustic impedance is displayed as a positive amplitude (black peaks) in the seismic cross section.

The focus of this 3D seismic study is from the late syn-rift in the Early Miocene to post rift phase one (I) in the Middle Miocene, 0.2-1.5 second two-way time (TWT) in Sequences 3 and 4 of **Figure 25**. The faults and three key horizons (S1-late Early Miocene, S2-top Early Miocene, and S8-top Late Miocene) were interpreted and mapped throughout the 3D full stack seismic reflection data. The results were used to extract various seismic attributes. In order to map the variations in vertical reservoir distribution and seismic geomorphology, additional strata slices were generated with reference to the three key horizons. The strata slices are proportional subdivisions of the interval between two horizons. Due to the low-amplitude discontinuous reflectors caused by low acoustic impedance contrast of sands and shales and the structural complexity of western boundary faults, it was extremely difficult to interpret chrono-stratigraphic surfaces, and phantom horizons were generated to aid the interpretation.

**Figure 25** Stratigraphy of the Songkhla Basin tied to an example of 3D seismic reflection data and the gamma ray log of the representative well with the study interval in the blue block.

**Figure 26** (a) Seismic cross section line AA' displays eight (8) selected horizons, S1-S8 in relation to the stratigraphic sequences of Songkhla Basin, sequence 3-5 (SQ3-SQ5) and the gamma ray log of the representative well. (b) Uninterpreted seismic cross section. (c) Time structural map on S1 horizon, late Early Miocene, displays seismic cross section line AA' location

Rock physics analysis and seismic attribute analysis are the two main techniques applied to this study after traditional seismic interpretation (structural and horizon mapping) was completed for the basin. Rock physics analysis was applied to establish the link between seismic amplitudes to geological facies and reservoir properties (e.g. Goodway et al., 1997; Connolly, 1999; see review in Bacon and Simm, 2014). P-wave

velocity ( $V_p$  or primary wave), S-wave velocity ( $V_s$  or secondary wave), density ( $\rho$ ), and acoustic impedance (AI) were derived from well log data at well locations to determine rock properties that can be used to discriminate lithology, sands and shales. The cluster separation of these parameters on cross plots was used to identify lithological facies. If the separation of facies using AI cross-plots at well log scale is poor, then such facies discrimination at the seismic scale is also likely to be poor.

Seismic attributes are very useful for the structural interpretation and reservoir characterization apart from the traditional seismic interpretation. Good seismic attributes are directly sensitive to the changes in seismic impedance and allow structure and depositional environments to be defined (Brown, 2004; Chopra and Marfurt, 2005). In this study, a series of different seismic attributes were extracted along the interpreted horizons to aid the structural interpretation, reservoir distribution identification and their related meaningful geological features. The seismic attributes successfully used in this study were similarity, root mean square (RMS), and spectral decomposition. All these attributes were compared with the GR logs at blind test well locations to check the relationship between attributes and the reservoir zones.

Similarity and coherency, are computed based on changes in wave trace shape or both amplitude and shape, and are useful attributes for imaging subtle faults and the edges of fluvial channels and reefs (Bahorich, 1995; Marfurt et al., 1999; Ahmad and Rowell, 2012; Ahmad et al., 2014; Ghosh et al., 2014). In this study, the similarity attribute was extracted from horizons of interest in the syn-rift interval using IHS Kingdom 2014 (**Figure 27**). The attribute revealed low to moderate sinuosity, parallel, dark lines (non-similarity) set in broad white/light grey color zones of high similarity that mainly coincide with the main depocenter located in the south-western part of the study area (**Figure 27 (a)**). These sinuous features are associated with low amplitude channel-like features, surrounded by high amplitudes in vertical seismic sections, interpreted as mud filled channels (**Figure 27 (c)**). Therefore, the sinuous features are interpreted as channel edges. **Figure 27** shows the relationship of the similarity with the RMS attributes extracted from S1 horizon, and the seismic amplitudes in cross sections. Similarity maps can be integrated with the RMS and spectral decomposition attributes to provide more accuracy when mapping the reservoir distributions.

Root Mean Square (RMS) is a statistical measurement of the magnitude of amplitude variations over a data set by computing the square root of the sum of squared amplitudes divided by the number of samples within the specific window interval. RMS is very sensitive to amplitude variations, therefore, it emphasizes the variations in acoustic impedance in the selected window. A change of AI is assumed to be mainly due to a lithology change. Commonly, the higher the acoustic impedance variation, the higher the RMS values will be.

**Figure 27** Examples of sinuous features associated with the S1 interval. (a) Similarity map shows channel-like boundaries. (b) RMS map displays sand distribution with channel-like features. (c) Vertical seismic amplitudes section along line AB shows low amplitudes channel features surrounded by high amplitudes that are interpreted as mud-filled channels. These

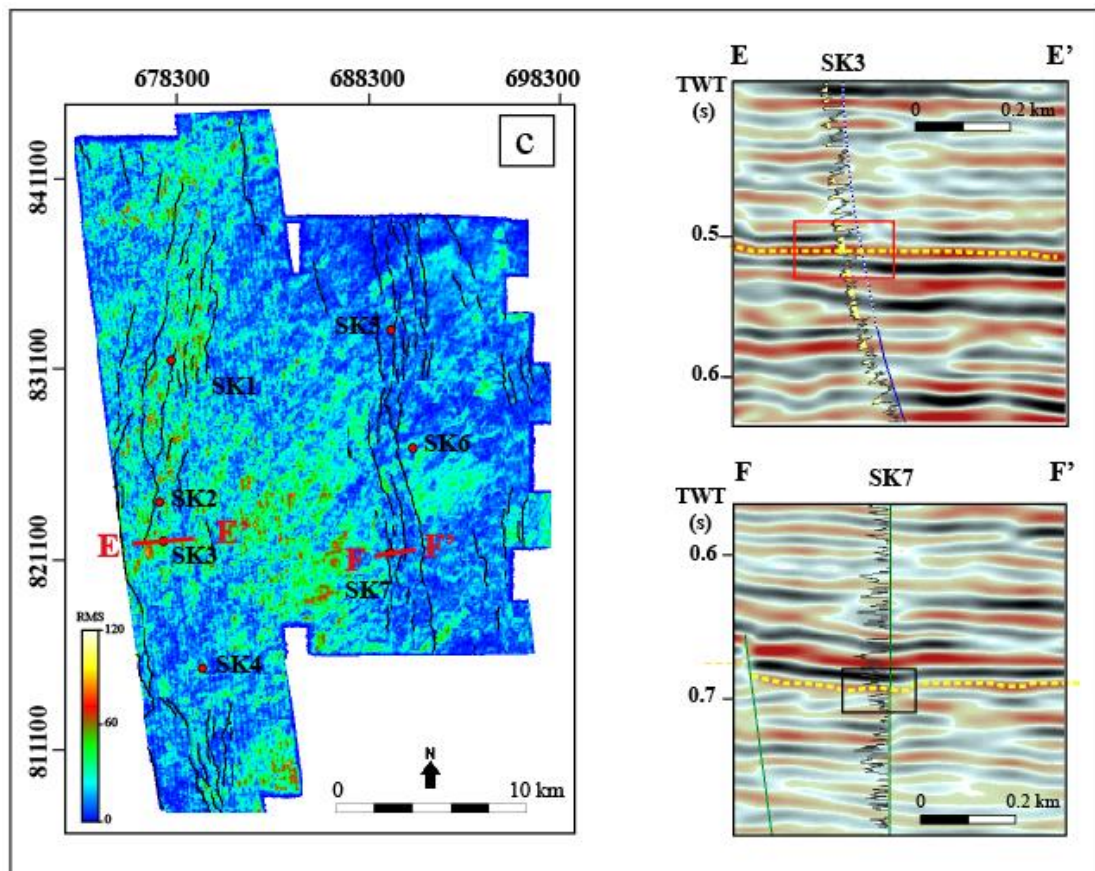

channels are located at A and B, their edges are well seen on the similarity map, (a).

The RMS attributes extracted from the interpreted major horizons in the study area displayed meaningful geological features, channel-liked patterns and reservoir distribution, throughout the interval of interest of the late syn-rift and post-rift phase I, where high amplitude contrasts are present. High RMS values on maps correspond to the sands at well locations, as confirmed by the blind test wells that penetrated high amplitude areas (**Figure 28 (a), (b), (c)**). The late syn-rift section exhibits good images of channel-like features in the southern part of the basin (**Figure 28 (a), (b)**), while for post-rift phase I (**Figure 28 (c)**), good images of reservoir distribution are present in the middle and northeastern parts of the basin.

Spectral decomposition (SD) attributes are generated by the transformation of a seismogram (seismic signal) to a frequency domain of the seismic bandwidth (Partika et al., 1999; Brown, 2004). Spectral decomposition can provide highly detailed images of the reservoir related to subtle changes in bed thickness (Payton et al., 1998; Laughlin et al., 2002; Liu and Marfurt, 2007; Matos et al., 2005). Bed thickness and geological discontinuities within the seismic survey are identified by breaking down the seismic signal into its' component frequencies (Partika et al., 1999; Marfurt and Kirlin, 2001; Sinha et al., 2005). In this study, 3D seismic data were transformed into iso-frequency domains using discrete fourier transforms (DFT) by applying the SD Trace Sub-band method (SD) in the short window range of 20-40 ms. The RMS amplitude spectra extracted from selected iso-frequency SD volumes display scattered anomalies along faults and unfaulted zones in the study area. Different sand thicknesses show the highest amplitude spectra at different frequencies ranging between 20 Hz – 80 Hz. The interval of interest has a tuning thickness of 25 meters at 25 Hz frequency. The 40 and 63 Hz frequencies offer the best imaging of channels (**Figure 29**). The RGB (red-green-blue) blending techniques were applied to the multiple frequencies to display different meaningful geological features detected by different frequencies. Frequencies of 20, 40, and 63 Hz were chosen for the RGB (red-green-blue) color blending.

**Figure 28** The relationship of the RMS maps, seismic amplitudes, and the lithology interpreted from gamma ray log characteristics at well locations on S1, S2, and S4 horizons (a) S1 RMS amplitude map (b) S2 RMS amplitude map (c) S4 RMS amplitude map: cross sections AA', CC', and EE' showing high RMS values, warm colors, correspond to sands at well locations and high amplitude contrasts in the seismic reflection data, where cross sections BB', DD', and FF' showing low RMS values, cold colors, correspond to shales at well locations with low amplitude contrasts in seismic reflection data. (add). SK1, SK2, SK3, SK7 are wells with gamma ray log with the GR scale of 0-300 API (left-right).

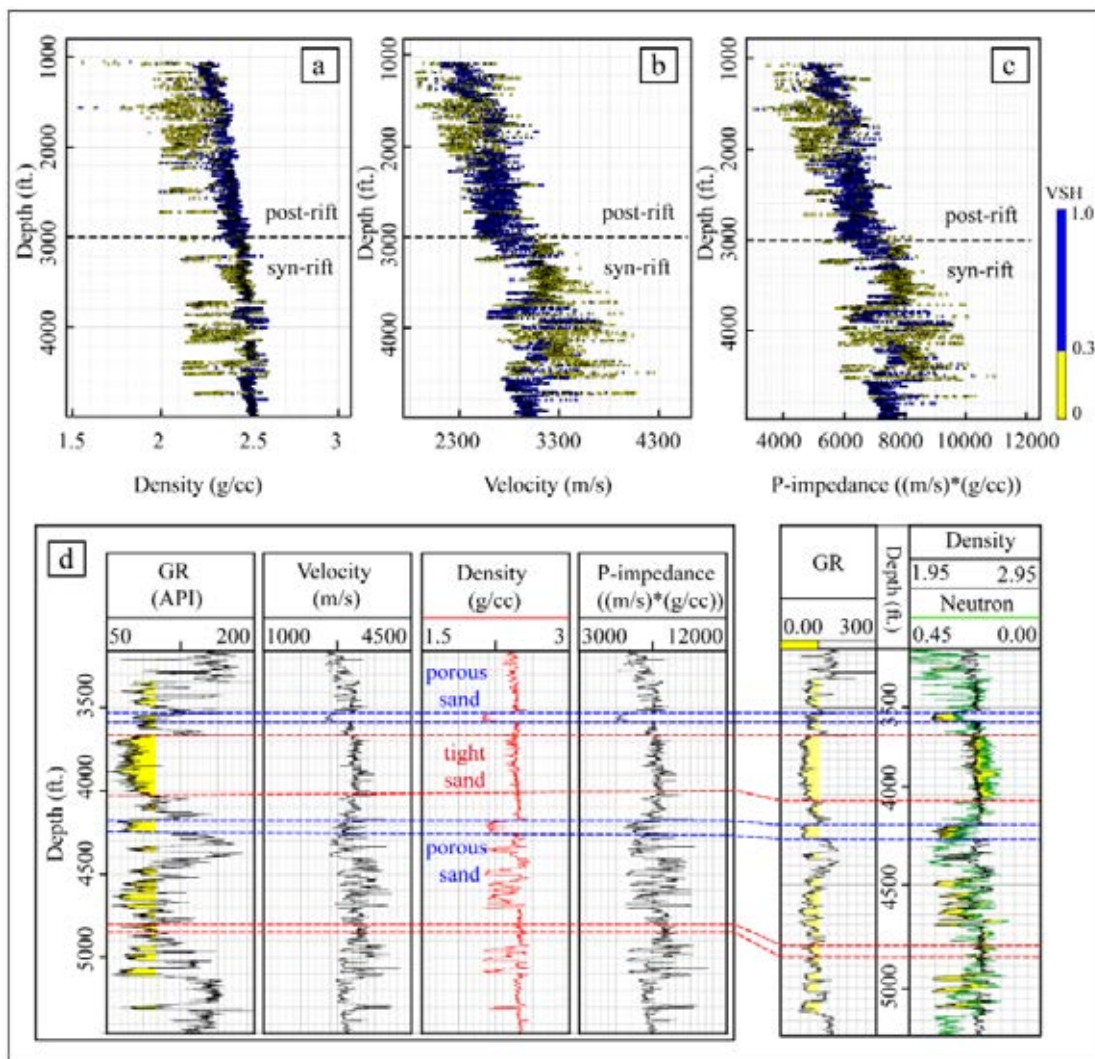

**Figure 29** Example of SD Trace Sub-band of S2 horizon at 20 Hz (a), 40 Hz (b), and 63 Hz (c). These frequencies displayed the best channel images compare to other frequencies. In (b) and (c) different parts of channels are highlighted by the red dotted line with the red arrows. (d) and (e) displayed zoom-ins of un-interpreted channel-like features from (b) and (c).

### 5.3 Rock physics analysis

The cross-plots of rock physics parameters (density, P-wave velocity, P-impedance) versus depth with respect to shale volume are shown in **Figure 30 (a) to (c)**. The results from a few key wells, where the data and the interpretation are most integrated and reliable, indicate that generally the density trends of sand and shale increases with depth, where overall sands are of lower density than shales in the both

late syn-rift (upper Early Miocene) and post-rift (Middle Miocene) sections. Density increases with depth and follows similar trends to velocity and acoustic impedance (Figure 30 (a), (b), (c)). However, a number of tight sands in the syn-rift section show high density, velocities, and acoustic impedance, similar to shale. Therefore, P-impedance can be used to discriminate sands and shale in the shallow post-rift sequence from 1000-2300 feet (0.3-0.5 s TWT). While in the syn-rift, impedance cannot be used to differentiate tight sands and shale.

**Figure 30** Cross-plots of (a) Density (b) Velocity (c) P-impedance against depth (ft. TVDSS) with respect to shale volume at well SK1. (d) Correlation analysis between gamma ray (GR), velocity, density, P-impedance and density and neutron crossover show the relationship of the tight and porous sand at well SK1 in the late syn-rift interval (S1-S2).

## 5.4 Seismic attributes analysis – Findings

### 5.5.1 S1 Horizon (Early Miocene)

S1 is the lowermost horizon of the upper Early Miocene syn-rift phase II interval (**Figure 26 (a)**), where meaningful geological features were readily imaged and analyzed (channel-like features and reservoir distribution). The calculated RMS on the S1 horizon displays scattered high amplitude anomalies all over the study area, especially in the eastern and southern parts of the basin, with the overall N-S trend similar to that of the major western boundary fault zone. These high RMS anomalies are associated with sands, while low RMS values are associated with shale at well locations (**Figure 28 (a)**). The RMS map of the S1 horizon lacks clear images of channel-like features (**Figure 31 (a)**), but instead shows possible oxbow lake features in the southern part of the basin. Clearer images of channels and oxbow lakes were displayed on the SD volume at 40 Hz (**Figure 31 (b)**), while the channel boundaries are well-defined on the similarity volume (**Figure 31 (c)**), especially in the main depocenter, while the eastern and north-eastern areas display dim-images of channel edges.

Overlay of the RMS and similarity maps provides a good image of the channel shapes (**Figure 31 (d)**). While the RGB blending of three different frequencies (20, 40, and 63 Hz) from spectral decomposition provides better images of channel geometries compared to other attributes (**Figure 31 (e)**) as it combines together the different channels delineated in different frequencies. **Figure 31 (f)** illustrates the interpretation of channels and abandoned oxbow lakes. Integration of the RMS, similarity, and spectral decomposition shows that the channels in the S1 horizon have low to medium sinuosity, 1.2 sinuosity index (SI), especially in the main depocenter, where the channels follow NNW-SSE to N-S directions that correspond with the main fault strike directions. These channels are relatively wide (300-400 meters). The gamma ray (GR) log characteristics from the representative wells at this horizon show sands forming mainly blocky patterns, with some fining upwards patterns (**Figure 32**). Biostratigraphic data (pollen and spores, including Magnastriatites) from the delineation wells suggest the dominance of the fluvial depositional environment with

no evidence of lakes. Channels developed in this period are interpreted as meandering channels developed in a channel complex.

**Figure 31** Comparison of extracted attributes for the S1 horizon (a) RMS amplitude map (b) SD Trace Sub-band at 40 Hz map (c) similarity map, which delineated different geological features. (d) The overlay of RMS and similarity helps confirm channel boundaries. (e) RGB blending of SD 20, 40, and 63 display better image of channels. (f) Interpretation of the channels and abandoned oxbow lakes.

**Figure 32** West to east well correlation panel during late syn-rift to post-rift. The overall gamma log pattern displays sand prone in syn-rift and more shaley lithology toward post-rift I and to the east of a basin.

### 5.5.2 S2 Horizon (Early Miocene)

S2 is the uppermost horizon of Early Miocene syn-rift phase II. High RMS amplitudes were observed in the western areas along the major boundary faults, especially in the main depocenter located in the southern half of a basin (**Figure 33 (a)**, **Figure 34 (a)**). The high RMS amplitude extractions are associated with sand deposits confirmed by the correlation of the high RMS values with the sandstone interval in representative wells (**Figure 28 (b)**). Although the channel-like features could not be imaged on RMS data, meaningful geological features, i.e. shape of pointbar accretion are presented (**Figure 34 (a)**). The integration with similarity data provides better images of channels as the channel edges are displayed as parallel, narrow black lines of low similarity (**Figure 34 (b)**). The correlated features on the vertical seismic sections

reveal channel-like patterns with both high amplitude sand filled-channel and low amplitude mud filled-channels (**Figure 34 (c)**).

**Figure 33** The extracted attribute maps for the S2 horizon displayed channel-like features in the main depocenter, south-western part, adjacent to major western boundary faults on the RMS map (a), SD 40 Hz map (b), and the channel edges on the similarity map (c).

The shapes of the channels were better imaged by high SD frequencies (isofrequencies of 40 and 63 Hz). The observation shows that at 40 Hz frequency the southern channel is better displayed (**Figure 35 (a)**), while at 63 Hz frequency the northern channel is better displayed (**Figure 35 (b)**). The RGB visualization technique helped to combine these channels at different frequencies together (**Figure 35 (c)**).

**Figure 34** The relationship of the channel-like features on the RMS map (a), the channel edges on the similarity map (b), and the sand-and mud-filled channels in the seismic cross section (c).

**Figure 35** SD and RGB maps of S2 horizon (a) SD Trace Sub-band 40 Hz displays the southern part of a channel. (b) SD Trace Sub-band 63 Hz displays the northern part of channel. (c) The RGB blending of SD Trace Sub-band 20, 40, 63 Hz combines the two channels present in different frequencies.

S2 period channels are slightly wider (400-500 m) compared with the S1 period (300-400 m), with high sinuosity ( $SI = 1.8$ ) and follow the N-S to NE-SW strike of the western boundary fault zone. The gamma ray log from well locations shows the horizon has mostly sandstone, but with more shale compared to horizon S1, with a variety of log patterns i.e. fining upward, blocky, and coarsening upward (**Figure 32**). Integration of all attributes indicates the channels are meandering.

### 5.5.3 S3-S4 Horizon (lower Middle Miocene: early post-rift phase I)

S3 is the deepest horizon of the Middle Miocene post-rift phase I. The RMS amplitude map displays scattered high RMS anomalies, mainly in the southwestern area (main depocenter-along major boundary faults), and in the eastern part of the basin (**Figure 36 (a)**). These high amplitude anomalies are associated with sands at well locations (**Figure 28 (c)**). Images of small, channel-like features were observed in two areas: 1) the northwestern area along the western boundary faults, where channels with a N-S trend follow the strike of the western boundary fault zone, and 2) in the middle part of

the basin where channels trend NE-SW, slightly oblique to the boundary fault strike. Similarity on horizons S3 and S4 did not image the small channel edges probably due to resolution issues.

The geometries and orientations of the small channels are better imaged for the S4 horizon than S3 (**Figure 36 (b)**). The channels trend NE-SW, and are mainly developed in the middle part of the basin. The GR logs between horizons S3 and S4 show mainly high GR values, indicating sediments are mostly shale (**Figure 32**) compare to the higher sand content for the syn-rift phase II. Unpublished biostratigraphic data from the final well reports show the palynomorphs recovered (spores and pollen) were mainly fresh water at SK2 and SK4 wells and mangroves (*Spinizonocolpites* and *Zonocostites*) from the SK5-SK7 wells. These data indicate that during the early Middle Miocene (S3-S4 horizons), the basin was dominantly freshwater, especially in the southwestern area, while the eastern part experienced the onset of episodes of marine influence.

**Figure 36** RMS maps showing development of channels in the post-rift section I (Middle Miocene), a) horizon S3, b) horizon S4, c) horizon S5, d) horizon S6, e) horizon S7.

#### 5.5.4 S5-S7 Horizons (upper Middle Miocene: late post-rift phase I)

S5-S7 horizons are located in the upper interval of the Middle Miocene post-rift phase I. The RMS maps display a number of long, narrow bands of high amplitude anomalies in the middle part of a basin, which is the main depocenter during this period. These anomalies have low-medium sinuosity ( $SI= 1-1.15$ ) and developed in a NE-SW direction (**Figure 36 (c), (d), (e)**). The similarity attribute shows parallel, narrow, low-medium sinuosity, non-similarity (black lines) features between a region of high

similarity (white area), especially for horizons S6 and S7 (**Figure 37 (c)**). These white features are interpreted as pointbar sands that can also be observed on vertical seismic sections (**Figure 37 (a)**).

High RMS values that correspond to high amplitude contrasts in the vertical seismic section, are interpreted as small point bars associated with a small shale-filled channel belt. Low amplitude, mud-filled material surrounded by high amplitudes, which exhibit differential compaction, were also observed in vertical seismic sections (**Figure 37 (a)**). The interpreted channels in this period have widths between 200-300 meters. Unpublished, oil industry biostratigraphic studies indicate marine conditions occupied almost the entire basin as indicated by all wells, except SK4. In SK4 mangrove palynomorphs (*Spinizonocolpites*, *Zonocostites*, *Florschuetzia levipoli*, and *Florschuetzia meridionalis*) are dominant, which indicate the southwestern part of the basin still had freshwater conditions, with degrees of tidal influence. Therefore, during this period the basin exhibits more marine influenced deposition compared to the lower horizons, and is accompanied by higher average GR log values.

**Figure 37** a) Cross section line A-A' showing locations of channels with pointbar development on the S7 horizon. b) RMS map showing high amplitudes that correlate with pointbar sands. c) Similarity map showing subtle indications of channel boundaries.

## 5.5 Discussion

### 5.6.1 Depositional environment

The results from integration of various seismic attributes (RMS, spectral decomposition and similarity), show that significant differences in channel characteristics and morphology exist between the late syn-rift and post-rift phase I. Therefore, it is interpreted that for these intervals the Songkhla Basin exhibits two fundamental depositional patterns (**Figure 38**). The first depositional pattern comprises fluvial channels developed in the late syn-rift, upper Early Miocene (S1 and S2 horizons) interval characterized by a dominance of sandstone on GR log data, while biostratigraphic data from sidewall cores indicates low energy fluvial conditions without marine influence (**Figure 38 (a)** and **(b)**). The integration of all seismic attributes indicate that the lower S1 horizon channels were developed in a meandering channel complex with low sinuosity as displayed by the oxbow lakes cut by channels, which suggests a process of channel straightening (**Figure 38 (a)**). Whereas, the upper S2 horizon displays higher sinuosity channels that are slightly wider compare to the S1 period (**Table 2**). There is thought to be a strong relationship between slope angle and sinuosity, with sinuosity increasing as slope angle decreases passing from straight channels to meandering channels, as slope decreases further and braided channels develop sinuosity decreases (Schumm and Khan, 1972). Although the channels in S1 and S2 have very different sinuosity index values, both are interpreted as having been deposited within a meandering fluvial system in a low relief area. The difference in sinuosity index value depends on which channel shapes are preserved in the geological record. When meandering channels are preserved prior to oxbow lake development, the sinuosity index (S2) is high. If the oxbow lakes have formed and the straighten channels are preserved in geological record, the sinuosity index will appear to be low (S1) although the depositional environment is also within the meandering fluvial system.

Horizon	Channel width (m)			Channel depth (m)			Width/Depth ratio	Meander belt width (km)	Sinuosity Index (SI=CL/ML)	Channel pattern
	min	mean	max	min	mean	max				
S1 - late syn-rift (lower Early Miocene)	150	360	500	18	27	34	15	5	1.2	low sinuous
S2 - late syn-rift (upper Early Miocene)	210	450	600	23	28	39	17	7.5	1.85	meandering
S3-S7 - post-rift I (Middle Miocene)	110	230	350	15	22	31	11	1.5-2	1-1.1	low sinuous

**Table 2** Comparison of channel width, depth, width/depth ratio, meander belt width, sinuosity, and patterns during late syn-rift and post-rift phase I.

The second depositional pattern found in the Songkhla Basin comprises fluvial channels associated with deltaic and tidal depositional environments in the post-rift phase I section (**Figure 38 (c) and (d)**). The results of seismic attributes integrated with well data and biostratigraphy reveals fluvial channels developed close to the major boundary faults in the southwestern part of the basin during the beginning of the post-rift stage. During the early Middle Miocene (S3-S4 horizons), the basin was dominantly freshwater, especially in the southwestern part, while biostratigraphy indicates the eastern area started to experience episodes of marine influence. Later, in the upper Middle Miocene (S6-S7 horizons) the channel geometries evolved to higher sinuosity with more marine influence across almost the entire basin indicating by mangrove palynomorphs in all wells, except SK4.

**Figure 38** Conceptual model of depositional environment development in the Songkhla Basin from the late syn-rift (late Early Miocene) to post-rift I (Middle Miocene). (a) S1-lower late syn-rift horizon. Fault controlled western boundary fault margin, with axial fluvial channel-dominated depocentre in boundary fault hangingwall. Minor conjugate fault sets near flexural margin (b) S2-upper late syn-rift horizon. Declining boundary fault activity, with axial channel fluvial system in similar position to a). (c) S4-lower post-rift I horizon. Mild inversion of the boundary fault forces depocentre to the east. Smaller channels compared with a, and b are developed that trend NE-SW to NNE-S. Marine incursions enter from the NE part of the basin. SW (d) S7-upper post-rift I horizon. Post-rift subsidence depocentre focused in eastern-central part of basin, boundary fault morphology largely covered. Small N-S

to NNE-SSW trending channels developed with widespread marine incursions.

### **5.6.2 Tectonic influence on channel morphology**

Tectonic processes in rift basins exert an important role in controlling rift geometries and stratigraphic successions throughout their evolution from rift initiation to post-rift subsidence (Bosworth and McClay, 2001; Baudon et al., 2009; Bridge and Leeder, 1979; Gupta and Cowie, 2000; Karp et al., 2012; Lambiase, 1990; Lambiase and Bosworth, 1995; Lambiase and Morley, 1999; Leeder and Gawthorpe, 1987; Leeder and Jackson, 1993; McClay and Khalil, 2009; Olsen, 1990; Prosser, 1993, Williams and Dobb, 1993; Withjack et al., 2002). The Songkhla basin is part of a rift system whose period of transition from the syn-rift to the post-rift stage does not coincide with a neighboring region undergoing continental breakup. Instead, the syn-rift to post-rift transition, which is regionally diachronous (Morley et al., 2011), is probably related to 1) the varied and complex combination of factors causing extensional stresses (Pubellier and Morley, 2014), and 2) the mechanics of the lithosphere evolution during rifting that can cause some rifts to cease activity (strain hardening) while others can continue to extend (e.g. Kuszniir and Park, Corti et al., 2019). In general sedimentation rates in the Gulf of Thailand remained high through the Early-Middle Miocene, and declined during the Late Miocene-Recent as the climate became dryer and the winter monsoon became stronger across Asia (Clift, 2006). Overall there is remarkably little variation in water depth throughout the Miocene-Recent in the GOT (near sea level, maximum of 80 m water depth today), which reflects sedimentation rates and subsidence rates being locked in tandem, and is highly suggestive of subsidence being largely controlled by sedimentation rates (Morley and Westaway, 2006). The upper Early Miocene stratigraphic successions in Songkhla basin is considered to represent the last stage of the rift cessation due to the subaerial depositional environment of fluvial channels (that replaced earlier shale-prone lacustrine-lagoonal deposition) prior to the transition to the fluvio-deltaic deposits of the Middle Miocene post-rift section.

Sedimentary deposits, which were developed in the late syn-rift, upper Early Miocene (S1 and S2 horizons), are characterized by basinwide channel systems with low to high sinuosity large-scale channel belts with individual channels stacked together. These channels are concentrated in the main depocenter in the hangingwall of active major extensional boundary faults with the main flow directions along the strike of the faults. These relationships indicate boundary fault-controlled sedimentation and minor river avulsion with downslope cut-off, resulting in wide channel belt sandbodies, which in other basins have been interpreted as a gradual response to slow tectonic subsidence (e.g. Alexander and Leeder 1987; Leeder and Gawthorpe, 1987; Leeder and Jackson, 1993). During this waning stage of extensional activity in the region, the decreasing extensional strain was mostly accommodated on the major western boundary fault system (Phoosongsee and Morley, 2018) indicating that tectonics still controlled basin subsidence during this time. For the North Sea, McLeod et al. (2002) discuss how differential tectonic subsidence has a strong control on the facies distribution and depositional patterns during the syn-rift period. In the Songkhla Basin meandering channels become wider and exhibit higher sinuosity from S1 to S2 reflecting the decrease in accommodation space and decrease of the slope from the eastern flexural margin toward the footwall uplift on the boundary fault margin as a result of slow tectonic subsidence rate before extension ended.

The regional syn-rift paleogeography (**Figure 39 (a)**) shows that north of the Songkhla Basin a branch of the Ko Kra Ridge runs between the Ko Kra Basin and the Nakhon Basin, and this ridge could be a source of sediment from the north into the Songkhla Basin, as well as from the east into the flexural margin. While the existing high area today, Peninsular Thailand, could have supplied sediment from the west and south. Probably the footwall high area along the western boundary fault margin of the basin would have prevented most of the sediment from the west from entering the basin, and instead have deflected that sediment northwards to the Nakhon Basin. The NNW-SSE to N-S channel orientations following major western boundary faults strike indicate these drainage systems could arise either from paleohighs to the north of the basin, or from Peninsular Thailand to the south.

**Figure 39** The regional syn-rift paleogeography map illustrating potential directions of river flow, as indicated by the blue arrows, from highlands to basin lows.

The second depositional pattern found in the Songkhla Basin is related to fluvial channels associated with deltaic and tidal depositional environments during post-rift phase I. During the beginning of the post-rift stage, channels are observed in the southwestern part of the area close to the western boundary faults (S3). These channels were relatively small, but can be seen on the seismic attributes (Fig. 12) as having NE-SW orientations. The change in channel directions to a NE-SW trend was probably caused by the changes of slope accompanying migration of depocenters away from the western boundary faults toward the east of a basin that probably resulted from mild inversion that occurred after the termination of extension (Phoosogsee and Morley, 2018). It is uncertain whether these channels were sourced from the western boundary fault margin or from the eastern, flexural margin. We favor a source from the west, assuming that as displacement declined on the western boundary fault margin topography became lower, enabling river systems to enter from the west. Additionally, with marine incursions entering the NE part of the basin it can be concluded that the topography to the north and east of the basin had become degraded and lowered to permit such incursions, making a sediment source from that direction unlikely (**Figure**

**39 (b)**). A higher density of small narrow channel belts is present during the later post-rift period and they trend NNE-SSW (S4-S7) flowing away from western boundary faults to the new depocenter that migrated from west to east in the basin during post-rift thermal subsidence. Biostratigraphy for the early Middle Miocene indicates the southwestern part of the basin was dominantly freshwater with varying degrees of subareal exposure and intertidal episodes defined by the spores and pollen and mangrove elements. Subsequently, in the late Middle Miocene (S6-S7) the eastern basin had transitioned to intertidal, upper estuarine and lower coastal plain margin depositional environments.

Climate change is another important factor that could potentially influence channel morphology as it controls the river discharge and sediment delivery, which affects the fluvial response (Miall, 2002). Based on Morley (2012), the period from Early Miocene to Middle Miocene (i.e., syn- to post-rift transition period of Songkhla Basin) experienced the same moist monsoonal climate regime covering much of the Sunda and East Asian region (**Figure 40**). This East Asian monsoon for wetter climates was initiated by the closure of the Indonesian Throughflow following the collision of Australian Plate with Sunda at the end of Oligocene (Morley, 2012). Zachos et al., 2001, stated the earliest Early Miocene is characterized by an abundance of sands that resulted from erosion at the time of the sea level fall from the J1000 horizon of the Malay Basin (Morley, 2012). This sequence may be equivalent to the late Early Miocene in Songkhla Basin as it also contains abundant of sands (**Figure 32**) reflecting the high sediment charge during the everwet climate. However, in the Middle Miocene, the region experienced the Middle Miocene thermal maximum (Morley, 2012) with the continuation of the everwet climate. Yet sand input to the Songkhla Basin decreased, coincident with post-rift subsidence and the development of lower-relief regionally, accompanied by an increase in the frequency of marine incursions into the basin. With a consistent wet climate throughout the Early to Middle Miocene, there is no clear link between the paleoclimate and channel morphology variations in the Songkhla Basin, the variations observed are more closely linked with tectonics during the syn-rift to post-rift transition.

**Figure 40** Oxygen isotope curve of Zachos et al. (2001) compared to the major tectonic and climate, including the study interval from S1 (late Early Miocene) to S7 (Middle Miocene).

The syn-rift post-rift transition in the Songkhla basin is characterized by a very gradual transition, both in the decrease in activity along the boundary faults (Phoosongsee and Morley, 2018) and in the change in depositional environments. Some of the changes, in particular channel orientation are related to reorganization of topography within the basin (particular due to inversion of the boundary fault zone hanging wall), while others, such as increasing frequency of marine incursions are related to eustatic events and tectonic subsidence which operated beyond the confines of the Songkhla basin.

With a better reservoir characterization of the fluvial to tidal deposits, the orientation of the thin reservoirs (channelized and point bars) within the depocenter versus the faulting structure will allow a better positioning of the exploration, appraisal and development wells within the Songkhla Basin for this petroleum play.

Identification of channels and point bars will allow the potential for stratigraphic traps or combination structure-stratigraphic traps within the Songkhla Basin to be tested.

## CHAPTER VI

### CONCLUSIONS AND RECOMMENDATIONS

#### 6.1 Conclusions

Detail analysis of the reservoir characterization and distribution, and the depositional history in relation to the tectonostratigraphic evolution of Songkhla Basin significantly contribute our understanding of how tectonics controls sedimentation, especially during syn-rift to post-rift transition period.

Study of the major boundary fault displacement characteristics and evolution shows that the Songkhla Basin appears to represent an example of a predominantly orthogonal extension half graben, little affected by pre-existing fabrics, that developed in phases between the Late Eocene and the Early Miocene. The rift spans two phases of rifting, the Eocene-Oligocene phase that is present in the eastern GOT, and the Oligocene-Miocene phase that is present in the western GOT and onshore area. The tectonic phases that can be distinguished within the Songkhla basin are slightly different and comprise: (1) an early rift stage in the Eocene; (2) a late rift stage from Oligocene to Early Miocene; (3) post-rift Middle Miocene possibly with minor inversion; and, (4) post-rift Pliocene to recent.

The boundary fault is composed of five large segments (F1-F5). During the Eocene, the segments, except for F5, became hard linked, and generally by the end of the Eocene, throw conformed to the constant length, and coherent fault models. This observation adds to the growing body of literature that indicates the importance of these models in fault development (as reviewed by Jackson et al., 2016). During subsequent reactivation of the boundary fault system, the linkage points become more apparent in the throw-length profiles, and the later throw patterns during waning extensional activity tend to follow an isolated fault model as shown in **Figure 24**.

Two distinctive channel characteristics and patterns developed in two different periods: meandering channels developed in channel complexes during the late syn-rift (upper Early Miocene) and long narrow channel belts developed during post-rift phase I (Middle Miocene) indicating different mechanisms controlling sedimentation.

Tectonic is a major control on the channel development and reservoir distribution throughout rift evolution in Songkhla Basin. Channel development during the late syn-rift stage was mainly located in the depocenter adjacent to the major boundary faults and shows the same trend or slightly oblique trends to the fault strikes, suggesting that faults were still active at this stage, while during the post-rift stage, channels flowed to the new depocenter that had migrated eastwards from being adjacent to the western boundary faults in the syn-rift phase to the middle part of the basin in the post-rift phase. This shift is both a consequence of mild inversion along the boundary fault margin, and the location of maximum thermal subsidence.

By integrating seismic attributes and well interpretations to study subsurface preserved stratigraphy, it has been found that the Songkhla basin represents a very gradual syn- to post-rift transition in a coastal-transitional marine setting. The stratigraphy is controlled by both the decrease in activity along the boundary faults and the change in depositional environments. Although coastal-shallow marine depositional environments are complex due to the sub-aerial exposure involving erosion of the syn-rift topography, the stratigraphic succession throughout the transition in Songkhla basin was still be preserved. Based on literature review, this is a rare published example for the coastal-shallow marine transition period that are preserved in subsurface.

Meaningful geological features were successfully extracted from 3D seismic data using the RMS, similarity, and spectral decomposition i.e. sand distribution, channel boundaries, oxbow lakes, point bars. The integration of all seismic attributes helped to identify channel geometries. This approach is more efficient for identifying depositional patterns than conventional seismic reflection data. This methodology can be applied to other basins for both exploration and production purposes.

## **6.2 Recommendation for future research**

This study has achieved the main purposed of establishing the tectono-stratigraphic evolution of Songkhla Basin. The influence of geological structure to the channel morphology and distribution during syn- to post-rift transition on a basin scale is now well understood in the study area. However, at the local sub-basin scales, especially in the vicinity of the conjugate fault sets in the middle part of a basin the sedimentary development could be more complicated.

The present investigation helped identify the types of the seismic attributes that provide good images of the subsurface geomorphology i.e. RMS, similarity and spectral decomposition (SD), where the SD provides better images using the RGB blending technique of different frequencies. Due to the software limitation, the SD being used in this study is the traditional discrete Fourier transform (DFT) that has fixed time-frequency resolution over the entire time frequency plane. Therefore, it is recommended to use the continuous wavelet transform (CWT) to produce better time-frequency maps as theoretically it has the ability to adjust window length and does not have fixed time-frequency resolution.

			220	22	10					
		River 10	290	26	11					
			340	19	18					
	300		27	11						
	150		25	6						
	200		19	11						
	River 11	260	15	17						
		350	19	18						
	S7	River 12	260	19	14	1.1	5.9	5.3	1.13	sinuous channel
			190	20	10					
260			22	12						
230			20	12						
230			18	13						
River 13		270	31	9		4.2	3.9	1.06	sinuous channel	
		260	24	11						

$$SI = \frac{\text{channel length (CL)}}{\text{meander wavelength (ML)}}$$

SI = sinuosity index

CL = channel length

ML = meandering wavelength

The sinuosity index has been used to separate channel rivers into three general classes:

1. Straight ( $SI < 1.05$ )
2. Sinuous ( $1.05 < SI < 1.5$ )
3. Meandering ( $SI > 1.5$ )

Example of channel measurement on S2 horizon

**APPENDIX E:  
BIOSTRATIGRAPHIC DATA**

- Fluvial depositional environment
- Fluvial with degree of marine influence
- Tidal influence - brackish water
- No data

**Biostratigraphic data on S1**

- Fluvial depositional environment
- Fluvial with degree of marine influence
- Tidal influence - brackish water
- No data

**Biostratigraphic data on S4 (lower post-rift I)**

- Fluvial depositional environment
- Fluvial with degree of marine influence
- Tidal influence - brackish water
- No data

**Biostratigraphic data on S7 (top of post-rift I)**
