Pimnapa Wongvisavakorn : The lead-lag relationship of Block Trade Single Stock Futures and the underlying stocks: Evidence from Thailand. Advisor: Asst. Prof. Dr. TANAKORN LIKITAPIWAT, Ph.D.

According to the efficient market hypothesis, there should not be any leadlag relationship of the spot and futures price of the financial assets; however, many empirical studies have suggested otherwise. This study uses the Vector Error Correction Model (VECM) and Granger causality test with the daily trading data of Thailand's block trade single stock futures and its underlying securities of 42 companies from 2016 to 2020. It reveals both unidirectional and bidirectional relationships of spot and futures markets with a less dominant role of the futures market in the price discovery function. None of the sample companies have both long-run and short-run causality from futures to spot market, and only $5 \%$ of the 42 companies show the leading role of the futures market in the long-run with bilateral interaction in the short-run. The results contradict our hypothesis that block trade single stock futures lead the counterpart underlying stocks in the short-run and longrun despite the higher leverage, lower transaction cost, and no short sale restriction of the futures market. The lead-lag relationship between block trade single stock futures and the underlying stocks in Thailand can provide insightful information for regulators and policymakers in promoting efficiency and improving the information asymmetry that would help create a better trading environment for investors.

## ACKNOWLEDGEMENTS

Writing this special project is much more difficult than I thought and more rewarding than ever imagined. Being a full-time employee in a securities firm and a parttime student in the MSF program is very much challenging especially during the COVID19 pandemic. This special project would not be completed without the help and guidance from the following persons. Firstly, I would like to express my deepest appreciation to Asst. Prof. Tanakorn Likitapiwat. Being his advisee is very fortunate not only from an academic point of view but also his devotion and understanding allowing for flexibility in communication and working conditions. I'm also deeply indebted to my committee, Asst. Prof. Ruttachai Seelajaroen and Assoc. Prof. Vimut Vanitcharearnthum for their valuable comments and constructive suggestions. Their questions have triggered me to think allowing me to fill in the missing aspects in my work. I cannot begin to express my thanks to Mr. Natapong Teekaput who is my MSF classmate. He has helped me a lot in the data collection process, his outstanding coding skill made it much easier for me to gather all the big data used in my analysis. Without him, this study would have taken a much longer time, or even impossible to start. I must also thank Mr. Paripon Sriboon who is also my MSF classmate. He has sent me books and answered most of my questions in econometrics, I am glad that we can share opinions to improve our work together. Completion of this project would not have been possible without the support from my colleague, Mr. Thanakorn Chongsuksirichoke who covered my work whenever I need to spend extra time on this project. He always cheers me up when things are out of the plan and willing to give a fresh eye opinion on my work. Most importantly, I am extremely grateful for being the only daughter in our family. My parents are unbelievably opened to whatever path I choose; they have always given unwavering supports and inspired me to fearlessly overcome any obstacles.

## 1. INTRODUCTION

There are currently more than 2,600 listed equity-related securities that can be exchanged in the SET market while there are 138 futures and 1 index option being traded in the TFEX market. Thailand Futures Exchange (TFEX), a subsidiary of the Stock Exchange of Thailand (SET), was later established in May 2004 with continued development over time. SET50 Index futures were the first product launched in 2006 followed by the SET50 Index Options in October 2007. Single Stock Futures (SSF) was then launched in November 2008 having three well-established stocks namely PTT, PTTEP, and ADVANC as the underlying assets in the first batch, followed by an additional 11 SSF in June 2009. However, these stock futures did not get enough attention from investors having low trading activities. Therefore, on November 8, 2010, a "Block Trade" transaction was allowed on SSF when the transaction started to increase substantially with the support from more continuous launches reaching 121 stock futures in 2021. SET50 Index and Single Stock Futures are the two major products driving trading volume in the Thailand futures market as shown in Figure 1.

The studies of the interaction between spot and futures markets mainly concentrated on stock indices and commodities due to their prevalence and relatively higher trading activities in most of the developed markets. However, the rapid development of SSF has recently received more attention in developing markets; Thailand's success story of Single Stock Futures has interested many regulators, policymakers, and practitioners. Like other high leverage products, lower trading costs, and unrestricted short-sale property, many investors relate Block trade on SSF to create higher volatility of the counterpart underlying assets. Vichitcholchai (2018)studied the relationship and concluded that Block Trade on SSF in Thailand provides liquidity and stabilized the spot market for the underlying assets, not the other way around. Jain et al. (2019) studies the Indian market, where the stock futures and options markets are very liquid, and found a significant increase in volume before the earnings announcements. Luerchathorn (2017) showed the abnormally increase in short-selling activities before the earning announcements in the Thai market and find the evidence against Efficient Market Hypothesis in that there was a negative relationship between
short-selling trading in the pre-earnings announcements and earnings surprise, and short-sellers can predict the extreme negative earnings surprise. The lead-lag relationship has been studied by Judge and Reancharoen (2014), suggesting the leading role of the spot market using the TDEX as a proxy for SET50 index and SET50 index futures. This has raised the interesting question of how the information has been transmitted between the two markets, Block Trade on SSF and underlying securities in Thailand.

Figure 1: Annual Trading Volume in TFEX by product (numbers of contract)

Source: SETSMART

There are two types of trading transactions for SSF which are Automatic Order Matching (AOM) and Block Trade. AOM is the automatic process to match the order sent to the trading platform in which investors will have no information of the counterparty; on the contrary, Block Trade is the over-the-counter transaction that occurred from the negotiated party at the agreed volume and price. Specifically, Block trade for SSF in Thailand requires a minimum number of contracts for each transaction.

One contract is accounted for one thousand shares of the underlying stock and it differs in groups of stocks according to the announcement from TFEX as shown in Table 1

More than $90 \%$ of the recent trading volume of single stock futures in Thailand has come from Block Trade, which significantly dominates the futures market as shown in Table 2. Block trade on SSF was mainly traded by local investors having similar functions to put-through transactions in the spot market. Table 3 shows the investor participation in Single Stock Futures since 2011; the SSF market has been dominated by the local players. This supports the recent meaning of Block trade on SSF, it is the big lot trade on SSF where a minimum number of contracts is exchanged over the counter having the broker members as a counterparty for any investors. Individuals can participate easily by placing collateral not less than the initial margin and sending an order to buy or sell an underlying asset not less than a minimum number of the contract specified by Thailand Clearing House Co., Ltd. (TCH). The counterparty broker members usually hedge the position through the spot market; therefore, we can assume some relationship between the two markets. Empirical studies in Thailand by

Muntanaveerakul et al. (2020) have suggested that Single Stock Futures trading reduces volatilities in their counterpart's spot market.

Table 3: Trading Volume of Single Stock futures by investor type

In an efficient market, all publicly available information will be reflected in the security price. Assuming risk neutrality and rationality, any new information will be reflected in the two markets simultaneously. Any speculative activities would generate zero abnormal return; in other words, there is no existence of predictability. Thus, the lead-lag relationship between the futures and spot market doesn't exist. Empirically, despite the advanced development of the cointegration technique, it is difficult to conclude the relationship between the spot and futures prices. Various studies have revealed the conflicting relationship between the two markets. The studies of S\&P 500 \& FTSE 100 (Wahab \& Lashgari, 1993), Malaysian stock market (Zakaria \& Shamsuddin, 2012), and Turkish stock market (Kasman \& Kasman, 2008) suggested the long-run dominant role of spot returns while some researchers have shown that futures price movement leads the index movement in short-run such as Nasdaq 100 (Hasbrouck, 2003), S\&P 500 (Chu et al., 1999; Kawaller et al., 1987; Niederhoffer \&

Zeckhauser, 1980; Pizzi et al., 1998), DAX (Booth et al., 1999), FTSE 100 (Abhyankar, 1995; Booth et al., 1999), and S\&P CNX Nifty (Pati \& Rajib, 2011). Moreover, some also found the bidirectional relationship between index and futures such as S\&P 500 (Pizzi et al., 1998), Turkish market (Özen et al., 2009), and Hang Seng (Rajaguru \& Pattnayak, 2007).

The development of block trade on single stock futures and comparable trading volume to stock index futures have made Thailand a unique case study to unfold the interaction between single stock futures and their pairs in the spot market, focusing on how the new information being processed by both markets. In other words, the study is aimed to reveal the existence of the lead-lag relationship between the market for block trade SSF and underlying securities.

The vibrant market for SSF in Thailand might be due to the lack of stock options products, and the absence of an active or efficient stock-lending together with the advantages of futures products that have low transaction costs, unrestricted short-sale activities, and high leverage nature. Therefore, the hypothesis of this empirical study in Thailand is the block trade single stock futures leads the counterpart underlying stocks.

CMA
cexyese
The results from the study will shed light on how information is absorbed by different markets which could explain the investors' trading behavior and reveal the better-informed investor. Regulators, policymakers, and investors can use the results to better promote market efficiency. The Framework is drawn upon the daily data of single stock futures in TFEX and their underlying stocks in SET. The period starts from the first trading day of 2016 to a few days before the muted market at the end of the year ( $4^{\text {th }}$ January 2016 to $22^{\text {nd }}$ December 2020). All data for 121 pairs will be collected from SETSMART and the pairs that have inadequate daily trading data will be filtered out.

## 2. LITERATURE REVIEW

### 2.1 Efficient Market Hypothesis

According to Fama (1970), in an efficient market, stocks and their associated derivatives such as futures and options will fully respond to the arrival of new publicly available information instantaneously and simultaneously. Many recent empirical studies found counteract pieces of evidence and many emphasized the unrealistic and strong assumptions of EMH and have shown that the real market is far from fully efficient.

Grossman and Stiglitz (1980) found that the price cannot fully reflect all available information because the information is costly. The action to find and gather information must receive the compensation, thus the market is far from perfectly informationally efficient. Similarly, Cutler et al. (1988) and Black (1986) found that information arrival cannot fully explain the movement in the market; Black (1986) has also shown that "noise traders", who trade using everything else other than the information, contribute to the market liquidity. French and Roll (1986) suggested that the higher price volatility during träding hours can be explained using private information. Moreover, trading strategies such as buying past winners and selling past losers proposed by Jegadeesh and Titman (1993), and value strategies proposed by Lakonishok et al. (1994) can earn abnormal returns.
2.2 Price discovery and Spot-Futures market interaction

### 2.2.1 Stock Index and Stock Index futures

The long-run dominant role of the spot market is supported by many studies; for example, Wahab and Lashgari (1993) have shown that there is a unidirectional relationship of the index market leading the futures market in S\&P 500 \& FTSE 100. Similarly, Zakaria and Shamsuddin (2012), and Kasman and Kasman (2008) also found the leading role of the spot market in the Malaysian stock market, and the Turkish stock
market respectively. On the contrary, some researchers have proposed the other end of the direction which shows the short-run dominant role of the futures market; Nasdaq 100 (Hasbrouck, 2003), S\&P 500 (Chu et al., 1999; Kawaller et al., 1987; Niederhoffer \& Zeckhauser, 1980; Pizzi et al., 1998), DAX (Booth et al., 1999), FTSE 100 (Abhyankar, 1995; Booth et al., 1999), and S\&P CNX Nifty (Pati \& Rajib, 2011). However, a study by Pizzi et al. (1998) has suggested a bidirectional relationship between S\&P 500 index and S\&P 500 index futures. This relationship also found in the Turkish market (Özen et al., 2009), and Hang Seng market (Rajaguru \& Pattnayak, 2007). Using intraday quoted price for SET50 Index and traded prices of SET50 Index Futures and TDEX, CHIYACHANTANA et al. (2012) found the existence of long-run relationship among the three markets and concluded the market efficiency can be improved through the multi-market trading of the derivatives market and its underlying. SET50 Index futures contributes the most in price discovery, followed by SET50 Index, and the least in TDEX.

### 2.2.2 Commodities

Markets for Commodities are also active and liquid in derivatives trading, Mahalik et al. (2009) studied price discovery and volatility spillovers of the commodity market and futures market in India and found that futures market (MCX) for Agricultures, Energy, and Aggregate commodity has price discovery function in the spot market while metal has no price discovery function. Liu and Zhang (2006) have shown the dominant role of price discovery in Chinese commodity futures markets for Copper, Aluminium, Soybean, Rubber, and wheat.

Attentions have been given to the relationship between the stock index and stock index futures, and commodities market, yet the results are mixed and unique to the market condition. Much of the studies also focus on the developed markets due to the longer establishment and higher liquidity; however, a different setting to the younger markets where there are many recent developments on derivatives products might also help reveal the unanswered questions.

### 2.2.3 Single Stock Futures

Single Stock Futures are one of the growing products in many Asian countries. While Korea, India, and Thailand are so vibrant in SSF trading as shown in Figure 2, SSF trading activities in most developed countries are relatively low; Jones and Brooks (2005) found that the lack of liquidity and transaction may lead to poor execution and fulfillment for hedging and speculating purposes in the US market. However, Shastri et al. (2008) used the data from OneChicago and found the decreasing share in the price discovery process when the volatility in the spot market and the relative spread of the futures market to the spot market rise. Fung and Tse (2008) suggested that SSF has accounted for $33 \%$ of price discovery despite the low trading volume using intraday data from Hong Kong Exchange. Bilateral interaction also observed from the papers from Kumar and Tse (2009) while Srinivasan (2009) found 43\% of the SSF samples in India that the futures market has the leading role, $28.5 \%$ of the sample that the spot market has the leading role, and $28.5 \%$ has bilateral interaction. There is also a study in Taiwan by Songyoo (2012); it shows a bilateral interaction in the long run, and the futures market leads the spot market in the short run. Moreover, some studies involve the determinant of the SSF trading volume; for example, Bialkowski and Jakubowski (2012) have shown that institutional holdings, volatility, and trading volume of the underlying stocks in the spot market are the significant factor to the trading activities on SSF using the data from the Eurex Exchange.

## 3. DATA

The Framework is drawn upon the daily data of single stock futures in TFEX and their underlying stocks in SET. The period starts from the first trading day of 2016 to a few days before the muted market at the end of the year ( $4^{\text {th }}$ January 2016 to $22^{\text {nd }}$ December 2020). All data for 121 pairs will be collected from SETSMART, and the pairs that have insufficient daily trading data will be filtered out.

Daily traded prices for block trade single stock futures and underlying stocks will be collected as shown in the example in Figure 3 and Figure 4. For the SSF, there are four contracts available at any time, H series for ending in March, M series for ending in June, U series for ending in September, and Z series for ending in December. The nearest maturity will be used since it is the most active contract with the highest trading volume to avoid the illiquidity problem. The data from the next series will be used 4 days before the last trading day of the current series, following the real data patterns and method employed by Judge and Reancharoen (2014).

## 4. METHODOLOGY

### 4.1 Stationary Test

For time-series data, it is crucial to test for stationarity of the variables first, nonstationary data in a regression model can give us spurious regression results that are misleading and wrongly interpreted. Variables that are random and have no relationship among them can generate significant results with a high degree of $R^{2}$. To prevent this misrepresentation, it is a common econometric practice to do the stationary test first. Augmented Dickey-Fuller test will be employed here in this study, expecting the price series of spot and futures to be non-stationary, integrated of order one.

### 4.2 Cointegration Test

Granger (1981) brought in the concept of cointegration in that two nonstationary variables may move together if there are cointegrated. If such cointegration exists, there is a long-run relationship between them meaning that the two variables cannot be far apart, and any deviation in the short-run will reverse back to the equilibrium. In our study, if the spot and futures price are cointegrated, there exists a long-run relationship and the error correction representation.

Following Judge and Reancharoen (2014), Spot and futures price have earned their theoretical relationship through the cost-of-carry model:

$$
\begin{equation*}
F_{t}^{*}=S_{t} e^{(r-d)(T-t)} \tag{1}
\end{equation*}
$$

where $F_{t}^{*}$ is the fair price of block trade single stock futures at day $t, S_{t}$ is the spot price at day $t, r$ is the risk free-rate, $d$ is the dividend yield until maturity, and $T-t$ is the number of days to maturity of the futures contract. Stoll and Whaley (1990) and Brooks et al. (2001) have suggested that the market force which drives the cost-of-carry model is the never-ending search for free lunch. Arbitrageurs will act and close any deviation from the relation.

Therefore, relying on the cost-of-carry model, the integration between the spot and futures price is therefore strengthened by the arbitrage activity (Chan et al., 1991). Taking natural logarithms of both side of the equation (1) to transform into the linear form:

$$
\begin{equation*}
f_{t}^{*}=s_{t}+(r-d)(T-t) \tag{2}
\end{equation*}
$$

where $f_{t}^{*}$ is the natural logarithm of the fair price of block trade single stock futures, $s_{t}$ is the natural logarithm of the spot price. Equation (2) suggests the one-to-one longrun relationship between the natural logarithm of spot and futures price. Therefore, $f_{t}^{*}$ and $s_{t}$ are expected to be non-stationary, integrated of order 1 while the first difference of $f_{t}^{*}$ and $s_{t}$ are expected to be stationary, integrated of order zero.

However, the cointegration test will be performed using Engle and Granger's two-step method to test for cointegration according to Engle and Granger (1987). Following the relationship in the cost-of-carry model in (1) and (2) focusing on the long-run equilibrium relationship between single stock futures and the underlying stock, the cointegration error is defined as $\hat{\lambda}_{t}$ where

$$
\begin{equation*}
\hat{\lambda}_{t}=f_{t}^{*}-\hat{\beta}_{1} s_{t}-\hat{\beta}_{0} \tag{3}
\end{equation*}
$$

The second step is to test for stationarity of the estimated residual in the first step, the estimated cointegration error $\left(\hat{\lambda}_{t}\right)$, using the ADF test. In the case of stationary cointegration error, we can conclude that the natural logarithm of spot and block trade single stock futures prices are cointegrated. Thus, the return of stock and block trade single stock futures are expected to be used instead.

$$
\begin{align*}
& R_{f, t}=\ln \left(\frac{F_{t}}{F_{t-1}}\right)=f_{t}-f_{t-1}=\Delta f_{t}  \tag{4}\\
& R_{s, t}=\ln \left(\frac{s_{t}}{s_{t-1}}\right)=s_{t}-s_{t-1}=\Delta s_{t} \tag{5}
\end{align*}
$$

### 4.3 Vector Error Correction Model (VECM)

The optimal number of lags will be obtained using the VAR lag selection. Various information criterions such as AIC (Akaike Information Criterion), and BIC (Bayesian Information Criterion) will be considered in optimal lag selection to be used in the Vector error correction model. According to Judge and Reancharoen (2014) who studied the relationship between SET50 index futures and SET50 index, they obtained 2 lags from VAR lag selection while CHIYACHANTANA et al. (2012) used nine lags.

Referring to Engle and Granger (1987), the cointegration price series can be shown as:

$$
\begin{equation*}
\Delta p_{t}=\gamma z_{t-1}+\sum_{j=1}^{k} A_{j} \Delta p_{t-j}+e_{t} \tag{6}
\end{equation*}
$$

where $\Delta p_{t}=\left[\begin{array}{l}p_{1, t}-p_{1, t-1} \\ p_{2, t}-p_{2, t-1}\end{array}\right]$, the error correction term is $z_{t-1}=p_{1, t-1}-\beta_{t} p_{2, t-1}$, and $e_{t}$ is a vector of serially uncorrelated residuals that have covariance matrix $\Omega$,

$$
\Omega=\left[\begin{array}{cc}
\sigma_{1}^{2} & \rho \sigma_{1} \sigma_{2} \\
\rho \sigma_{1} \sigma_{2} & \sigma_{2}^{2}
\end{array}\right]
$$

while $\beta=[1,-1]$ is the cointegration vectors and $\gamma$ is a non-zero error correction vector to tell the correction of the short-run error to the long-run equilibrium. In our case, the dynamic interaction between the cointegrated spot and block trade single stock futures prices using VECM is given as (7) and (8):
$\Delta f_{t}=\delta_{f}+\gamma_{f}\left(f_{t-1}-\beta_{1} s_{t-1}-\beta_{0}\right)+\sum_{i=1}^{l} a_{f 1 t-i} \Delta s_{t-i}+\sum_{i=1}^{l} a_{f 2 t-i} \Delta f_{t-i}+\varepsilon_{f, t}$
$\Delta s_{t}=\delta_{s}+\gamma_{s}\left(f_{t-1}-\beta_{1} s_{t-1}-\beta_{0}\right)+\sum_{i=1}^{l} a_{s 1 t-i} \Delta s_{t-i}+\sum_{i=1}^{l} a_{s 2 t-i} \Delta f_{t-i}+\varepsilon_{s, t}$
$\Delta f_{t}$ is the natural logarithm of return on the block trade single stock futures while $\Delta s_{t}$ is the natural logarithm of return on the counterpart stock at day $t$ as presented in equations (4) and (5) respectively. $l$ is the optimal lagged period. $\delta$ is $(2 \times 1)$ constant vector. $\beta_{1}=\left[\begin{array}{ll}1 & -1\end{array}\right]$ is the cointegrating vector and $\gamma=\left[\begin{array}{ll}\gamma_{s} & \gamma_{f}\end{array}\right]$
is the coefficient matrix for the error correction term. The absolute value of them explains the speed of adjustment of the short-run deviation to the long-run equilibrium. The summation of the error correction coefficient $(\gamma)$ must be greater than zero where $-1<\gamma_{f} \leq 0$ and $0 \leq \gamma_{s}<1$. At least one of the coefficients must be significantly different from zero if the variables are cointegrated or having a long-run relationship. The high absolute value of error correction coefficient $(\gamma)$ means the strong adjustment to the long-run equilibrium; on the contrary, the low absolute value implies that the market will slowly adjust from the deviation.

Although cointegration can explain the long-run relationship of the two variables, it does not specify the direction, the coefficient of the error correction term will help explain the relationship in the long run as shown in Table 4Error! Reference source not found.

Table 4: Summary of long-run relationship from error correction coefficients

| Coefficient |  | Significance |  |
| :---: | :---: | :---: | :---: |
| $-1<\gamma_{f} \leq 0$ | significant | significant | insignificant |
| $0 \leq \gamma_{s}<1$ | significant | insignificant | significance |
| Relationship | Bidirectional <br> relationship | Unidirectional, <br> Spot leads futures | Unidirectional, <br> Futures leads spot |

However, to be able to explain the relationship in the short run, an F-test on the coefficients of lagged independent variables will be performed. The F-test will be performed twice for each company by setting the first null hypothesis that all $a_{f 1 t-i}$ for $i=1,2,3, \ldots, i$ are zero in the equation (7), and the second null hypothesis that all $a_{s 2 t-i}$ for $i=1,2,3, \ldots, i$ are zero in the equation (8). In other words, if all coefficients of $\Delta s_{t-i}$ in equation (7) is statistically different from zero (we reject the null hypothesis) and all coefficients of $\Delta f_{t-i}$ in equation (8) is not statistically different from zero (we cannot reject the null hypothesis), we can conclude that spot leading futures price. However, if all coefficients of $\Delta f_{t-i}$ in equation (8) is statistically different from zero (we reject
the null hypothesis) and all coefficients of $\Delta s_{t-i}$ in equation (7) is not statistically different from zero (we cannot reject the null hypothesis), we can conclude that futures leading spot price.

Unidirectional causality from spot market (S) to futures market (F) can be verified if the set of estimated coefficients of the lagged S are significant and the estimated coefficients of error correction term are significant, but the estimated coefficients of lagged F are not significantly different from zero. In our case, a oneway relationship of futures leading spot market would require $a_{s 2}$ to be significant, $a_{f 1}$ to be insignificant, and $\gamma_{s}$ to be significant. On the contrary, spot leads futures market would require $a_{f 1}$ to be significant, $a_{s 2}$ to be insignificant, and $\gamma_{f}$ to be significant. Bidirectional causality requires the set of estimated coefficients of lagged $S$ and $F$ to be significant and the two error correction terms to be significant.

Our hypothesis is to observe the block trade single stocks futures lead the counterpart underlying stocks in the short-run and long run. Thus, we expect to observe a strong Unidirectional causality from the futures to spot market.

## 5. EMPIRICAL RESULTS

### 5.1 Introduction

Block trade single stock futures have a limitation on data in that trading activities might not occur every day; therefore, the trading prices of these futures are not fully available for the whole period of study even for stocks that are very high in liquidity and popular among traders. In our scope of 121 stocks and their counterparts, 42 pairs are suitable for testing. 76 pairs are excluded based on the missing information of more than $30 \%$ of the overall data in the period of study from $4^{\text {th }}$ January 2016 to $22^{\text {nd }}$ December 2020. Three pairs namely WHA, MTC, and PTG are also excluded because the block trade single stock futures of these securities have been put to market after 2016. Therefore, they have large contiguous missing data of 252,544 , and 252 points respectively. The summary table of data inclusion and inclusion is shown in Table 5.

Table 5: Summary of data availability in the period of study

Imperfect data is very common in reality, linear interpolation and extrapolation are utilized to fill the data gap in the mentioned period before proceeding with other steps to test the hypothesis. Logarithm transformation on both price series is implemented for more convenience to work with the hypothetical cost-of-carry model. We then proceed with the logarithmic form of the price level and the return form.

Each pair of stock and block trade single stock futures will be tested separately following the process i) Stationary test ii) Cointegration test iii) Vector Error Correction model, then the conclusion will be drawn upon these 42 pairs which will help us understand more of the interaction between the two markets in both long run and short run.

### 5.2 Descriptive Statistics

We examined the total 42 pairs; PTTEP has the most data points in our period of study, so it is selected as an example pair represented in Table 6 where $S$ is the spot
price and F is the corresponding current futures price (see Appendix A for all descriptive statistics). The two means are very similar while the standard deviation, and minimum and maximum values are also very close to each other. Normally distributed data requires zero skewness, 0.0622833 for spot price and 0.0413249 for block trade single stock futures price, which is slightly more than zero meaning that these two prices are skewed right. These prices also have a thinner tail than the case of normality as they are less than 3 on kurtosis.

Table 6: PTTEP Descriptive Statistics

|  |  | F |  |
| :--- | :--- | ---: | ---: |
| PTTEP | stats | F |  |
|  | min | 42.1200 | 42.6603 |
|  | max | 158.6400 | 158.5421 |
| mean | 103.5224 | 103.4817 |  |
|  | sd | 24.0283 | 23.9852 |
|  | skewness | 0.0577 | 0.0623 |
|  | kurtosis | 2.0779 | 2.0579 |

In Figure 5, line plotting of average traded stock price and block trade single stock futures of PTTEP shows a closely tracking behavior between the two price series as expected.

Figure 5: The daily average traded price of PTTEP stock and block trade single stock futures during the sample period

### 5.3 Stationary Test

To begin the testing of time series data, the Augmented Dickey-Fuller test will be performed to check the stationarity. A model selection in this process involves a combination of theory and visual inspection of data; a Random walk with no drift and no trend model is chosen as the most appropriate model in this study. Because it is more appropriate to use the Augmented Dickey-Fuller test, lagged variables have to be included in the model. The optimal number of lags using in the ADF test has no distinctive formula; however, the guidance from Schwert (1989) will be followed here. In his work, he suggested including a maximum of $12\left(\frac{T}{100}\right)^{1 / 4}$ lags where $T$ is the number of observations, $T$ is 1214 in this study; thus, 22 is used here for the ADF test. The decision to include too few lags can cause autocorrelation problems while too many
lags can lower the power of the test. However, 1 lag and 22 lags are tested to see if there is any change in the conclusion of stationary. From the result in Table 7, altering the lags included does change the test statistic, but it does not change the conclusion. For all 42 companies, we cannot reject the null hypothesis of having unit root at the price level ( $\ln F$ and $\ln S$ ), but we can reject the null hypothesis at the return level $\left(R_{S}\right.$ and $R_{F}$ ) or non-stationary $\mathrm{I}(1)$. For example, the Augmented Dickey-Fuller test statistic for PTTEP is -7.462 in the case of $R_{F}$ and -7.221 for $R_{S}$, which are statistically significant at $1 \%$ level.

Likewise, it can be observed from the data plot illustrated in Figure 6 that there is a strong potential for non-stationary in price level and stationary after the first difference.

Figure 6: Comparison of the price level and return format of PTTEP

To be able to specify the long-run relationship between spot and futures prices, we need to test whether these series are cointegrated. In common practice, the Johansen Cointegration test will be performed to identify how many relationships exist in the system; however, with just two series in the scope, we can employ Engle and Granger's two-step cointegration test. The results for all 42 companies are presented in Table 8. For example, PTTEP has the test statistic of -28.455, we can reject the null hypothesis of no cointegration at a $1 \%$ significant level. In other words, there exists a cointegration between spot and futures price, or they have a long-run relationship. According to the results in Table 8, all 42 companies can be concluded to have cointegration between spot and futures prices ( $\ln S$ and $\ln F$ ). It is worth noting that for Engle and Granger's
two-step cointegration test has its unique critical value. In this case, they are -3.905, 3.341, and -3.048 for $1 \%, 5 \%$, and $10 \%$

5.5 Vector Error Correction Model (VECM)

The Stationary test and the Cointegration test are the basic requirements for the Vector Error Correction Model. This model is used to reveal the dynamic correction of the cointegrating data series that could help build the understanding of the deviation and the correction to the long-run relationship. Because our price series are nonstationary I(1), and cointegrated, VECM is the most suitable model to be applied in this
study. Following equations (7) and (8), it is first to define the optimal lag length to be included in the model using the function embedded in the statistical software which is based on the Akaike Information Criterion (AIC). For example, the optimal lag length for PTTEP is 6 lags which are mainly based on Akaike Information Criterion (AIC). In this process, repetitions of testing using different lags are required to find the appropriate number of lags to be used in VECM.

$$
\begin{align*}
& \Delta f_{t}=\delta_{f}+\gamma_{f}\left(f_{t-1}-\beta_{1} s_{t-1}-\beta_{0}\right)+\sum_{i=1}^{l} a_{f 1 t-i} \Delta s_{t-i}+\sum_{i=1}^{l} a_{f 2 t-i} \Delta f_{t-i}+\varepsilon_{f, t}  \tag{7}\\
& \Delta s_{t}=\delta_{s}+\gamma_{s}\left(f_{t-1}-\beta_{1} s_{t-1}-\beta_{0}\right)+\sum_{i=1}^{l} a_{s 1 t-i} \Delta s_{t-i}+\sum_{i=1}^{l} a_{s 2 t-i} \Delta f_{t-i}+\varepsilon_{s, t} \tag{8}
\end{align*}
$$

For different pairs of securities, lag length could differ in each system depending on how many lag lengths could best fit the model. After defining the optimal lags (p), VECM will be specified with p-1 lags. The optimal lag length to be used in VECM, and the estimated coefficients of error correction terms, $\gamma_{f}$ and $\gamma_{s}$ for each company are summarized in Table 9 for all 42 companies. The coefficient of error correction term tells the correction of the deviation to a long-run equilibrium where the absolute value explains the speed of adjustment.

Using PTTEP as an example, 6 lags is appropriate based on AIC in VECM specification, the coefficient of error correction term $\left(\gamma_{f}\right)$ in equation (7) is -0.424 which is statistically significant at a $1 \%$ level, suggesting that the deviation from the long-run equilibrium on the previous day will be corrected at a convergence speed of $42.4 \%$ within today. The negative sign of the error correction term, $\gamma_{f}$ is as expected; this means that when there is a positive (negative) error in this period, the futures price will adjust downward (upward) in the next period to restore the equilibrium. On the other hand, the coefficient of error correction term $\left(\gamma_{s}\right)$ in equation (8) is positive, 0.415 , or a correction speed of $41.5 \%$ on the next day, but it is statistically insignificant. For BCH , the coefficient of error correction term in equation (7), $\gamma_{f}$ is -0.298 while $\gamma_{s}$ is 0.292 in equation (8); both are significant at $1 \%$ level. It can be interpreted that when there is a positive (negative) error in this period, the futures price will adjust downward (upward) in the next period at a convergence speed of $29.8 \%$ while the spot price will
upward (downward) at a convergence speed of $29.2 \%$ to restore the long-run equilibrium.

According to Granger (1988) there are two types of causality; (i) the long-run granger temporal causality which can be discovered from the error correction term in VECM, and (ii) the short-run temporal causality which can be determined from the lagged independent variables using the F-test for joint significance.
(i) Long-run dynamic

For long-run causality, it can be discovered using the result of the coefficient of error correction term in VECM. From Table 9, we found a long-run spot leading futures market relationship in 16 companies which are AAV, ADVANC, BTS, CBG, CPALL, HMPRO, IVL, KBANK, LH, PTT, SAWAD, SCB, SCC, and TRUE. The two companies; AMATA and PTTGC are observed to have futures leading the spot market while the rest of the 24 companies which are BANPU, BBL, BCH, BDMS, BEM, BH, BJC, BLAND, CK, CKP, CPF, CPN, DTAC, INTUCH, IRPC, JAS, KTB, MINT, SIRI, STA, STEC, TMB, TOP, and TU have a bilateral relationship in the long-run.

Table 9: Summary of lags and VECM's error correction coefficients to reveal longrun dynamic

Note: $\left({ }^{*}\right)$ testifies that values are significant at $10 \%$ level, $(* *)$ testifies that values are
significant at $5 \%$ level, $(* * *)$ testifies that values are significant at $1 \%$ level

## (ii) Short-run dynamic

To reveal the short-run relationship between spot and futures market, we need to test for all coefficients of lagged explanatory variables in equation (7) and (8), which denoted as $a_{f 1 t-i}$ and $a_{s 2 t-i}$ respectively. If all coefficients of $\Delta s_{t-i}$ in equation (7) is statistically different from zero (we reject the null hypothesis) and all coefficients of $\Delta f_{t-i}$ in equation (8) is not statistically different from zero (we cannot reject the null hypothesis), we can conclude that spot leading futures price. However, if all coefficients of $\Delta f_{t-i}$ in equation (8) is statistically different from zero (we reject the null hypothesis) and all coefficients of $\Delta s_{t-i}$ in equation (7) is not statistically different from zero (we cannot reject the null hypothesis), we can conclude that futures leading spot price. The F-test result is presented in Table 10.

We found short-run spot leading futures market in 18 companies which are AAV, ADVANC, BBL, BH, BTS, CK, CKP, CPALL, CPN, DTAC, INTUCH, IRPC, IVL, SIRI, STA, STEC, TU and TRUE while 23 companies, AMATA, AOT, BANPU, BCH, BEM, BJC, BLAND, CBG, CPF, HMPRO, JAS, KBANK, KTB, LH, MINT, PTT, PTTEP, PTTGC, SAWAD, SCB, SCC, TMB, and TOP have a bidirectional relationship between spot and futures market in the short run. Only BDMS that its futures lead the spot market in short run.

Note: $(*)$ testifies that values are significant at $10 \%$ level, $(* *)$ testifies that values are significant at $5 \%$ level, $\left({ }^{* * *)}\right.$ testifies that values are significant at $1 \%$ level

However, from the study of 42 pairs of securities in Thailand in both long-run and short-run relationship, $26 \%$ of the sample has a strong bidirectional relationship between spot and futures markets (BANPU, BCH, BEM, BJC, BLAND, CPF, JAS, KTB, MINT, TMB, and TOP), $14 \%$ of the sample show a strong unidirectional relationship of spot leads futures market (AAV, ADVANC, BTS, CPALL, IVL, and TRUE), $0 \%$ of the sample shows a unidirectional relationship of futures leads spot market.

For different relationships across time, we found $24 \%$ of the sample to have spot leading futures market in the long-run, but both markets interact with each other in the short-run while $5 \%$ of the sample have futures leading spot market in the long-run but bidirectional in the short run. There are $29 \%$ of the sample that has a bidirectional relationship in long run, but spot leads the futures market in the short run; however, there is only 2 percent of the sample shows a bidirectional relationship in the long run, but futures leads spot in the short run.

## 6. SUMMARY AND CONCLUSION

According to the efficient market hypothesis, there should not be any lead-lag relationship of the spot and futures price of the financial assets. For the case of stock futures and their underlying asset, it should follow the Cost-of-carry model, and arbitrage futures model; therefore, the change in spot prices and changes in futures prices are expected to happen simultaneously. However, many empirical pieces of evidence do not support these theories; Luerchathorn (2017) found that the short-sellers can predict the extreme negative earnings surprise in Thai market settings while Judge and Reancharoen (2014) found the lagged changes in spot price lead to changes in futures price using TDEX and SET50 index futures.

With the vibrant market of block trade single stock futures in Thailand, this study finds evidence against the Efficient market hypothesis. Vector Error Correction Model (VECM) has revealed both unidirectional and bidirectional relationship of spot and futures market. However, none of the companies have both long-run and short-run causality from futures to spot market, and only $5 \%$ of 42 companies show the leader role of the futures market in the long-run with bilateral interaction in the short-run. Likewise, only $2 \%$ of the companies show a bilateral relationship in the long run having futures lead spot market in the short run. The results are contradicting to our hypothesis which is to observe the block trade single stocks futures lead the counterpart underlying stocks in the short-run and long run.

Despite the advantage of futures market, we observe a less dominant role in the price discovery function. According to Jong and Donders (1998), they studied the Netherlands stock and futures market and found that options and cash markets are led by the futures market because of its higher leverage and lower transaction cost. Floros and Vougas (2007) found the leading role of a futures market in Greece due to lower transaction costs and more liquidity in the futures market. However, in this study using 42 companies listed in the Thai market, we have weak leadership of the futures market using block trade single stock futures. The possible explanation of this outcome could be the minimum contracts per transaction and its limited order execution. For block trade single stock futures, there is a minimum requirement of buying and selling the
product which is determined by Thailand Futures Exchange PCL. For example, it requires investors to open a position at least 20 contracts for a block of ADVANC which is equivalent to 20,000 shares or expose an investor to a size of 3.5 -million-baht worth of money, calculated at 175 baht per share. In addition, to send an order to buy or sell these products, investors must make a call to their brokers to execute the order. Unlike stocks and other futures products, investors cannot trade block trade single stock futures through the internet on their own. These examples of unique features might be the reason why block trade single stock futures are being led by the spot market. In addition, the Thai market is considered to be far from a mature state, traders and investors might also have a limited understanding of futures products due to their higher complexity compared to the products in the spot market. Therefore, we can conclude at the top level that the spot market has a leading role in the Thai market.
