# # 5772886623 : MAJOR CHEMICAL TECHNOLOGY

KEYWORD: chemical looping combustion, thermal efficiency, hydrodynamic behavior,  
sustainability assessment, emergy

Watchara Uraisakul :  
SUSTAINABILITY ASSESSMENT OF POWER PRODUCTION BY CHEMICAL LOOPING COMBUSTION. Advisor: Prof. PORNPOTE PIUMSOMBOON, Ph.D. Co-advisor: Assoc. Prof. BENJAPON CHALERMSINSUWAN, Ph.D.

This study investigated the chemical looping combustion (CLC) process improvement for power production from energy management, system hydrodynamics, and sustainability perspectives. In the first part, the  $3^k$  factorial design was used for systematically investigating the operating variables that affect the thermal efficiency of the CLC combined with the humid air gas turbine (HAT) cycle. A set of operating variables, A) pressure of the air reactor, B) air compressor stages number, C) air compression methods, and D) air flow rate, were explored. The result showed that the highest thermal efficiency was at 55.87 % when operated at (A) 15 atm, (B) 7 stages, (C) method 3, and (D) 61,000 kmol/hr. Moreover, the efficiency could be improved further to 57.67% by increasing the Ni loading to 28% (by weight). The second part, the dual circulating fluidized bed reactor (DCFBR), was selected for the CLC system and investigated its operation by 2-D computational fluid dynamics (CFD) simulation. For the solid fuel, the result showed that the low value of temperature and ratio of coal velocity to the weight of an oxygen carrier provided the best performance. For the gaseous fuel, the high pre-exponential factor, the low initial solid volume fraction, velocity, and  $\text{CH}_4$  mass fraction in feed increased temperature and conversion. The result also indicated that the operating conditions are crucial for suitable hydrodynamics achievement and the  $\text{CO}_2$  capture efficiency. In the last part, three analyses, which were energy performance, economics, and sustainability, were evaluated to identify the best case by enhancing the process sustainability. Six case studies have been investigated the effects of the combustion types (conventional combustion (CC) and CLC) and system configuration ( $\text{CO}_2$  capture stages and operating conditions). According to emergy analysis, which is the tool that gives a more holistic view of the solution than the others, Case 4 was the best case due to its emergy sustainability index (ESI), when local content was taken into consideration. However, Case 5 would be the best case from a global perspective.

## ACKNOWLEDGEMENTS

I would like to recognize the invaluable assistance that the following people all provided during my Ph.D study.

First of all, I wish to express my sincere appreciation to my advisor, Professor Dr. Pornpote piumsomboon, for structuring this research as well as quality control of this research. He was really involved in this project. His advice reinforces the strength and closes the weakness of the research. Eventually, the research is complete with high quality. He made me feel that we were one team. His words that got through a hard time were “The problem is the part of learning”. I would like to thank you for your support throughout my Ph.D study. I would like to recognize the invaluable assistance that the following people all provided during my study.

I wish to show my gratitude to my co-advisor, Associate professor Dr. Benjapon chalermnsinsuwan. He made me feel that everything in Ph.D life was not complicated at all.

Watchara Uraisakul

ABSTRACT (THAI).....	iii
ABSTRACT (ENGLISH) .....	iv
ACKNOWLEDGEMENTS.....	v
TABLE OF CONTENTS.....	vi
LIST OF TABLES.....	xiv
LIST OF FIGURES.....	xvii
Chapter 1 Sustainability assessment of power Production by chemical looping combustion .....	1
1.1. Background .....	1
1.2. Objectives.....	2
1.2.1. Study effect of operating conditions on power production with CLC process .....	2
1.2.2. Develop dual circulating fluidized bed reactor for CLC .....	2
1.2.3. Study economic feasibility and energy analysis .....	2
1.3. Scope of the investigation .....	2
Part I 2	
Part II.....	2
Part III.....	2
1.4. Benefit.....	2
Part I 2	
Part II.....	2

Part III.....	2
1.5. Methodology .....	3
Part I: The operation conditions for obtaining the optimal thermal efficiency of the system. ....	3
Part II: The hydrodynamics of dual fluidized bed reactor for chemical looping combustion reactor .....	3
Part III: The economic analysis and sustainability evaluation of chemical looping combustion.....	3
Chapter 2 Literature reviews .....	5
2.1. The types of CO <sub>2</sub> sequestrations .....	7
2.1.1. Post-combustion processes.....	7
2.1.2. Pre-combustion processes .....	8
2.1.3. Oxy-fuel combustion processes .....	8
2.2. Chemical looping combustion .....	9
2.2.1. The classified CLC by number of main reactors. ....	11
2.2.1.1. The two reactors system.....	11
2.2.1.2. The three reactors system .....	11
2.2.1.3. The multi-reactors system.....	12
2.2.2. The CLC using with a fuel cell.....	12
2.2.2.1. Solid oxide fuel cell (SOFC)/chemical looping-based system.....	12
2.2.2.2. Proton-exchange membrane fuel cells (PEMFC)/chemical looping-based system.....	14
2.2.3. The CLC for the utilization .....	15
2.2.3.1. Chemical looping reforming, CLR .....	15

2.2.3.2. Chemical looping hydrogen regeneration, CLHG.....	16
2.2.3.3. Chemical looping air separation, CLAS.....	16
2.2.3.4. Integrated chemical looping air separation, ICLAS .....	17
2.2.3.5. Chemical looping with oxygen uncoupling, CLOU .....	18
2.3. The oxygen carrier .....	19
2.4. The section for power production.....	19
2.4.1. Conventional steam cycles, SC .....	20
2.4.2. Combined cycle, CC .....	20
2.4.3. Steam injected gas turbine cycle, STIG cycle.....	21
2.4.4. Humid air turbine cycle, HAT cycle .....	22
2.5. Aspen plus program .....	23
2.6. The computational fluid dynamic.....	24
2.6.1. Eulerian-Eulerian method .....	24
2.6.2. Eulerian-Lagrangian method.....	25
2.7. Economic analysis .....	25
2.7.1. Equipment cost.....	26
2.7.2. Fixed capital investment cost, FCI .....	26
2.7.3. Total capital investment cost, TCI .....	27
2.7.4. The operation and maintenance costs [61] .....	28
2.7.5. The cost of administration, supervisor or laboratory .....	28
2.7.6. Depreciation cost .....	28
2.7.7. The significant indicator for economic analysis.....	29
2.7.7.1. Net present value (NPV) .....	29

2.7.7.2. Internal rate of return (IRR) .....	29
2.7.7.3. Breakeven point .....	29
2.7.7.4. Payback period .....	29
2.8. Sustainability evaluation.....	29
2.8.1. Unit energy values, UEV.....	30
2.8.2. Environmental loading ratio, ELR.....	31
2.8.3. Energy yield ratio, EYR.....	31
2.8.4. Energy sustainability index, ESI.....	32
2.9. The literature reviews .....	32
2.9.1. The investigation of the operation conditions .....	32
2.9.2. The investigation of the hydrodynamics.....	33
2.9.3. The investigation of Energy.....	34
Chapter 3 The methodology of this research .....	37
3.1 The methodology of chapter 4; the investigation of operating parameters of a CLC with HAT cycle process for power production.....	39
3.1.1 The research gaps .....	39
3.1.2 Objective .....	39
3.1.3 Methodology.....	40
3.1.3.1 Process description .....	40
3.1.3.2 Experimental design .....	42
3.1.3.3 Thermal efficiency .....	43
3.1.3.4 Method of air compression .....	44
3.2. The methodology of chapter 5; hydrodynamic behavior of chemical looping combustion .....	46

3.2.1 The research gaps .....	46
3.2.2 The objectives .....	46
3.2.3 Model description.....	47
3.2.4 The first section .....	49
3.2.4.1 Methodology for the first part.....	49
3.2.4.2. The equations for CFD simulation included of this followed. [98]... 51

## Chapter 1

### Sustainability assessment of power Production by chemical looping combustion

#### 1.1. Background

A greenhouse gas, mostly CO<sub>2</sub>, has been the most released gas from power production processes. Although the reduction of energy consumption is the true solution of this crisis, it is complicated to carry out because of the economic growth and population increase. Thus, one is searching for a technology that could provide power and heat with minimal impact to the environment. Chemical looping combustion (CLC) is a novel technology that could help the issue of CO<sub>2</sub> management. With this technology, the power generation will be more efficient and environmentally friendly. The CLC has two reacting units connecting each other, air and fuel reactors. In the air reactor, metal is oxidized by the air to produce metal oxide as an oxygen carrier. The oxygen carrier is transported from the air reactor to the fuel reactor and combusts directly with fuel. The products of the combustion are heat, steam, and carbon dioxide which is easily to separate. Carbon dioxide is separated from steam by condensation. Finally, the spent oxygen carrier is returned to regenerate in the air reactor. The carbon dioxide, which is high purity, will be sent to the storage. The power production system that is sustainable will not only supply to meet the demand, but also create positive impact to environment.

This study investigates operating conditions that will provide the highest efficiency of power production. The optimal operation condition of the CLC will increase the power production and worthiness of fuel usage. After obtaining the operating condition for the maximum power production, the hydrodynamics of CLC reactor was investigated further. The hydrodynamics data of the reactors were used to estimate the geometry of the reactors. However, the maximum thermal efficiency is not sufficient conclusion for sustainable investment. Eventually, the decision for construction and operation of a plant will have to consider both profit and environmental impact. The economic and sustainable analyses will be evaluated for the best decision. There are various methods for sustainability assessment. The energy analysis is a novel method for sustainability assessment. The method considers the impacts of materials, energy, money, and manpower on producing a product or services.

## 1.2.Objectives

- 1.2.1. Study effect of operating conditions on power production with CLC process
- 1.2.2. Develop dual circulating fluidized bed reactor for CLC
- 1.2.3. Study economic feasibility and emergy analysis

## 1.3. Scope of the investigation

### Part I

- The power production by chemical looping combustion with humid air gas turbine (HAT) cycle without CO<sub>2</sub> utilization

### Part II

- The 2-dimensional model of the dual circulating fluidized bed reactor (DCFBR) with full loop simulation for chemical looping combustion

### Part III

- The economic and sustainability analyses of a power plant at 50 MW (electrical) when it was located on Thailand

## 1.4. Benefit

### Part I

- The guideline for operating significant parameters to obtain the highest thermal efficiency.
- The investigation of the multi-stage compressor operation on the thermal efficiency of the system.
- The investigation of the work and heat integration of the CLC process for power production.

### Part II

- The complete-loop of DCFBR model for chemical looping combustion.
- The proper operating condition to obtain the suitable hydrodynamics behavior in DCFBR.

### Part III

- The comparison of 3 analyses; thermal efficiency, economic analysis and sustainability analysis.

- The sustainability comparison between the conventional combustion and chemical looping combustion.
- The guideline of the operation condition to achieve high sustainability.

### 1.5. Methodology

The sustainability evaluation of chemical looping combustion for power production was divided into 3 parts.

**Part I:** The operation conditions for obtaining the optimal thermal efficiency of the system.

The 3<sup>k</sup> factorial design was used to systematically conduct the experiment. All case studies were simulated by Aspen plus program version 8.8 at steady state condition. The four independent parameters were investigated including of pressure of air reactor, number stages of air compressors, methods of air compression and air flow rate. Four responses to be observed were thermal efficiency, power production from air reactor, work of air compressors and air compressor discharge temperature. The result in this part will be used as preliminary data for obtaining the optimum thermal efficiency in power production. After that, the optimum conditions were used to in next part.

**Part II:** The hydrodynamics of dual fluidized bed reactor for chemical looping combustion reactor

The result from part I was the optimum operating condition of the investigated process. For this part, the hydrodynamics inside the CLC reactor were investigated. The DCFBR model was developed by using the Ansys Fluent version 19.2. The model was used to gain the understanding of hydrodynamics and to estimate the size of chemical looping combustion reactor.

**Part III:** The economic analysis and sustainability evaluation of chemical looping combustion

The suitable case studies were selected from part I. The material and energy data from part I were used to conduct in economic and sustainability analyses. The capital and operating costs in economic analysis were calculated by using the process information obtained from part I. The emergy flow in sustainability analysis was also calculated by using the process information from part I. The size of reactor from part

It will affect to the purchased cost in this part. Furthermore, the sustainability evaluation of the CLC and conventional combustion were compared. The result from this part was the way to improve the chemical looping combustion process for power production.

## Chapter 2 Literature reviews

Electricity is one of the public utilities. It is a form of energy that is convenient to utilize. As a result of the population increase and economic growth, the trend of electricity demand is continuously increased. [1] The United States Environmental Protection Agency (EPA) reported that CO<sub>2</sub> was the highest species of greenhouse gas of U.S. [2] In addition, the international energy agency (IEA) reported that the power production was the potent source of greenhouse gas emissions of Thailand and World as shown in Fig. 2.1. [3]

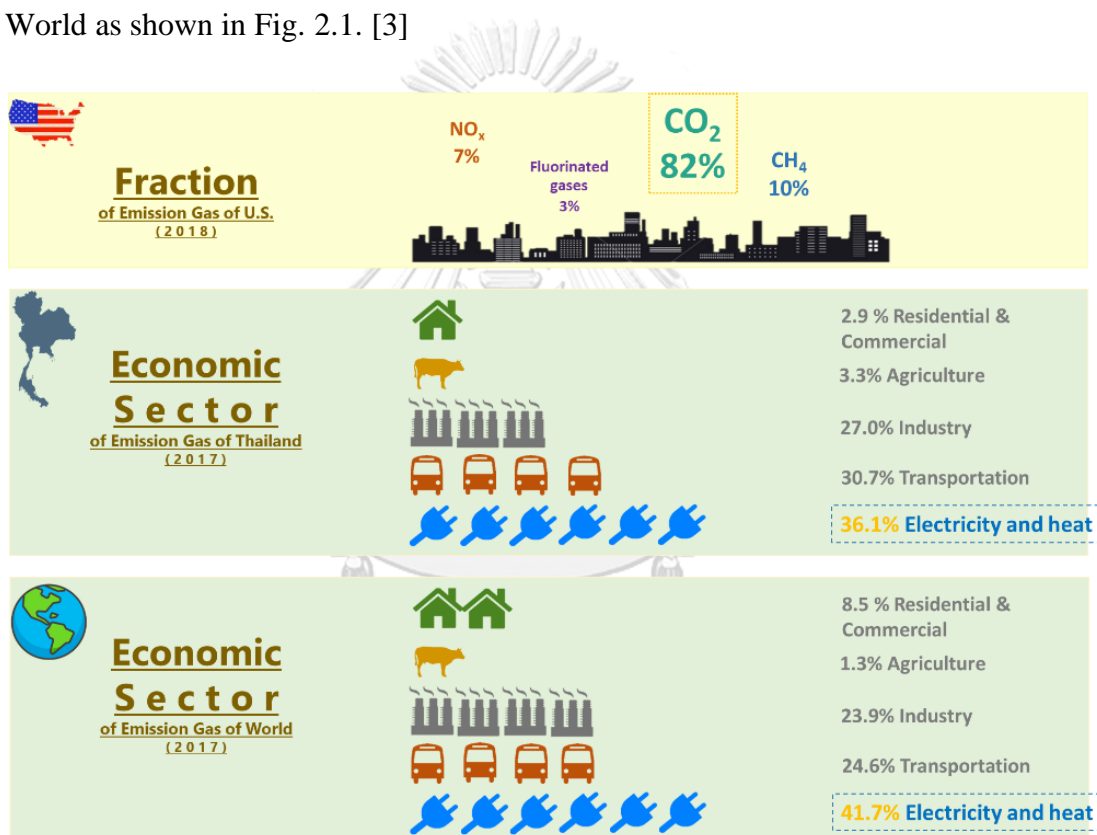

Fig. 2.1 Emission of greenhouse gas. [2, 3]

Accordingly, the power production for supporting the society demand is the reason of the global warming crisis. CO<sub>2</sub> is the highest fraction of the greenhouse gas. Electricity is directly produced by combusting a fuel (natural gas, coal, or fuel oil) with air in a combustion chamber to produce hot gas that is used to drive a gas turbine or to produce steam and use produced steam to drive turbine and a generator.

Therefore, the fuel combustion is typically the main source that releases large amount of CO<sub>2</sub> to the atmosphere and accelerates global warming effect. The quantity of the CO<sub>2</sub> in the flue gas that is released to the environment depends on the efficiency of a CO<sub>2</sub> capture process.

The environmental crisis and the natural resource depletion are key factors that stimulate the development of combustion technology and CO<sub>2</sub> mitigation technology. In the conventional combustion, fuel and air reacts with each other directly. For a power generation, its system efficiency without carbon capture and storage system (CCS) is only 25%. [4] Therefore, the thermal process to produce electricity should be improved to be more efficient and the process should also become a greener electricity production. There are several power production systems that have high energy conversion efficiency. The efficiency of the gas turbine combined cycle (GTCC) is 60%. After the post-combustion process, the efficiency is reduced by 8-10% due to energy penalty in CO<sub>2</sub> capture operation. [5]. The combined cycle of natural gas without the carbon capture and storage (CCS) has the efficiency of 58% , but the CCS process will reduce its efficiency by 10% [ 6 ] [7]. The technology for CCS is developed to reduce the CO<sub>2</sub> release to the environment. There are several CO<sub>2</sub> sequestrations available, such as pre-combustion, post-combustion and oxy-combustion technologies as shown in Fig. 2.2.

Fig. 2.2 The configuration of post-combustion, pre-combustion and oxy-combustion processes. [8]

## 2.1. The types of CO<sub>2</sub> sequestrations

### 2.1.1. Post-combustion processes

It is used to capture CO<sub>2</sub> in flue gas after combustion by sorbents such as K<sub>2</sub>CO<sub>3</sub> and MEA. This process has high efficiency in capturing CO<sub>2</sub> (more than 90%) depending on conditions or operations and reactors. The advantages of this method are high efficiency in capturing CO<sub>2</sub>, low cost investment, and no change of the original plant. [9] K<sub>2</sub>CO<sub>3</sub> is a promising solid sorbent for CO<sub>2</sub> capture process from flue gas because of high economic performance and stable capture performance. In addition, K<sub>2</sub>CO<sub>3</sub> requires low energy for regeneration. [10] The CO<sub>2</sub> is captured by K<sub>2</sub>CO<sub>3</sub> at 60-80°C and the sorbent can be regenerated at 120-200°C. [11] When comparing monoethanolamine (MEA) and K<sub>2</sub>CO<sub>3</sub> processes, it was found that the K<sub>2</sub>CO<sub>3</sub> process was lower heat of absorption and lower cost of investment. [12] Even though, amine absorption process is the mature of CO<sub>2</sub> capture process, [13] its main disadvantages are high energy consumption and material corrosion. [13] On the contrary, K<sub>2</sub>CO<sub>3</sub> was the good candidate of CO<sub>2</sub> capture process because of high CO<sub>2</sub>

capture efficiency, high cyclic usage, and low energy requirement for the adsorption. [14, 15] In this study, solid sorbent CO<sub>2</sub> capture process was selected for the power production case studies. because it was the best process in term of sustainability aspect for CO<sub>2</sub> capture process. [16]

The implement of a post-combustion CO<sub>2</sub> capture process with solid sorbents reduces the overall efficiency of power plants by 8.2–14.0%, mainly due to the solid sorbent regeneration section. [17] The type of post-combustion sequestration that provides the highest CO<sub>2</sub> capture efficiency is physical adsorption, because it is a reversible process. [16, 18, 19] The challenge of the post-combustion process is the operating condition at ambient pressure which is lower than the requirement of CO<sub>2</sub> compression. [8]

### **2.1.2. Pre-combustion processes**

It is used to capture CO<sub>2</sub> of fuel gas before combustion. This method widely uses in integrated gasification combined cycle (IGCC) and hydrogen (H<sub>2</sub>) production. There are two main unit operations: air separation unit (ASU) and gasification unit. ASU produces high purity of oxygen (O<sub>2</sub>) and sends to a gasifier. Syngas is produced by the gasifier at high temperature and high pressure. H<sub>2</sub>O is fed into a reactor for reacting with CO to produce H<sub>2</sub> and CO<sub>2</sub>. After that CO<sub>2</sub> is separated from H<sub>2</sub> by acid gas removal system. H<sub>2</sub> is used as fuel for power generation or other processes. This method produces high purity of H<sub>2</sub>, CO<sub>2</sub> and heat. The advantages of pre-combustion process are the high concentrated of CO<sub>2</sub> in syngas, operation condition at high pressure and lower energy consumption for CO<sub>2</sub> compression. [8] Moreover, the problem and challenge of pre-combustion process was to separate the undesired gases from syngas, especially CO<sub>2</sub>. [20] In addition, this technology was suitable for a new plant more than apply to the existing plant. However, ASU and gasifier require high energy and high-cost investment. Accordingly, this technology was mostly investigated in a small-scale plant. [21]

### **2.1.3. Oxy-fuel combustion processes**

It is used to capture pure CO<sub>2</sub> in flue gas by using pure O<sub>2</sub> to combust with a fuel instead of air. This method widely uses in a combustion process. The oxy fuel combustion has 3 main units of energy penalty installed : an air separation unit

(ASU), a compression unit and a purification unit (CPU). [22] ASU produces high purity of  $O_2$  and sends to combustion chamber. The flue gas composes with  $CO_2$  and  $H_2O$ . The 2/3 of total flue gas was recycle into combustion reactor for temperature maintaining because the material cannot be tolerated with high temperature from the combustion with pure  $O_2$ . [23]  $H_2O$  is separated from flue gas by condensation. Accordingly, it can separate very high  $CO_2$  concentration from flue gas. [8] The efficiency of this system is reduced due to the energy consumed in these units by 10-12% .The challenge of oxy-fuel combustion process is high energy consumption and high cost investment in the ASU requirement. [8] Each type of the  $CO_2$  capture process has different advantages and disadvantages.

The achievement of a CCS depends on the competence of the safety at the storage that it is not hazardous to the ecosystem. [23] The efficiency of a natural gas combined cycle before the  $CO_2$  capture process was reported to be 60%, whereas the efficiency of the process with a post-combustion, pre-combustion and oxy-combustion processes are 50%, 46% and 48%, respectively, with 85–90%  $CO_2$  removal. [7] In three technologies, it consumed additional energy which led to the reduction of the process efficiency.

## 2.2. Chemical looping combustion

Chemical looping combustion (CLC) is a novel technology that could help the issue of  $CO_2$  management. With this technology, the power generation will be environmentally friendly and be more efficient due to less energy penalty for the CCS. The CLC was the oxy-fuel combustion process that was developed for commercialization. [8] The resemblance between CLC and oxy-fuel is the reaction between only  $O_2$  and fuel. Oxygen carrier is the media that only carries the  $O_2$  from the air to oxidize with the fuel.

Mostly, the CLC has two reactors connecting to each other, air and fuel reactors. The principal of the CLC was showed in Fig. 2.3. In the air reactor, a metal is oxidized by the air to produce metal oxide as an oxygen carrier. The oxygen carrier is transported from the air reactor to the fuel reactor and combusted directly with the fuel. The products of the combustion are heat, steam, carbon dioxide which is easily to separate from the combustion gas, as shown in Eq. 2.1 and Eq. 2.2. There are 2

main components in flue gas which are  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . The water is separated from the flue gas by condensation and the remainder is high purity of  $\text{CO}_2$ . Finally, the spent oxygen carrier is returned to regenerate in the air reactor and the process is continued as a cycle. The CLC process is a high thermal efficiency for the power production, not because pure  $\text{O}_2$  is needed. It was because of the easiness of the  $\text{CO}_2$  separation in the flue gas. [24] The CLC process that use  $\text{H}_2$  as a fuel obtained very high thermal efficiency: 63.5%. [25] The efficiency of the CLC with combined cycle is 51% and increase to 53% when increased the temperature from 1,000 °C to 1,200 °C. [26] When increased the gas pressure by using multiple pressure levels of the turbines, one could utilize the heat in the exhausted gas from the turbines, reduce the loss of energy and increase the process efficiency. The maximum efficiency of Ibrahim's study was 55.2% [27] and Brandvoll's study was 55.9 [28]

Fig. 2.3 Principle of Chemical looping combustion (CLC). [29]

### 2.2.1. The classified CLC by number of main reactors.

When classified the CLC types by the number of the main reactors, there were 3 types; two, three and multi-reactors.

#### 2.2.1.1. The two reactors system

The process consisted of air reactor and fuel reactor as mentioned above. The oxidation reaction occurred in the air reactor. The reduction reaction occurred in the fuel reactor, as shown in Fig. 2.4.

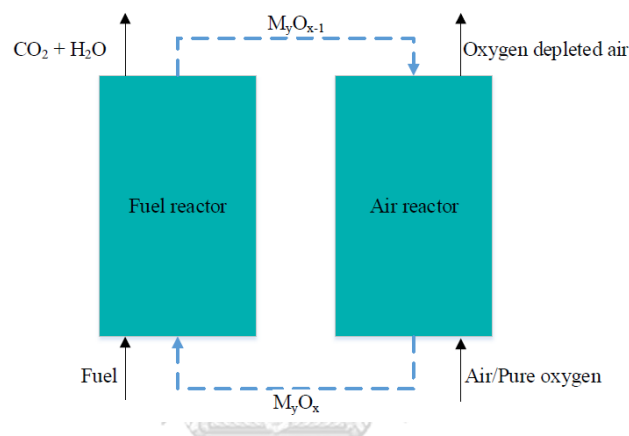

Fig. 2.4 The two reactors of the CLC system. [30]

#### 2.2.1.2. The three reactors system

This system is consisted of air reactor, fuel reactor and steam reactor, as shown in Fig.2.5. The steam reactor was used to produce  $H_2$ . [31] Firstly, fuel was reacted with oxygen carrier ( $M_yO_x$ ) in the fuel reactor. The products of the first step were  $CO_2$ ,  $H_2O$  and spent oxygen carrier ( $M_yO_{x-2}$ ). Next, steam was reacted with the spent oxygen carrier ( $M_yO_{x-2}$ ) in the steam reactor. The products of this step were  $H_2$ , excess  $H_2O$  and partially oxidized oxygen carrier ( $M_yO_{x-1}$ ). The last step, the partially oxidized oxygen carrier ( $M_yO_{x-1}$ ) was reacted with compressed air in the air reactor. The products of this step were oxygen carrier ( $M_yO_x$ ) and the excess air. After that the partially oxidized oxygen carrier ( $M_yO_{x-1}$ ) was regenerated and was used in a cyclic system again. The  $H_2O$  from the fuel reactor and the steam reactor were separated by the condensation process. The high purity of  $CO_2$  and  $H_2$  were obtained. The iron was also used as an oxygen carrier that might be suitable for this process. [31]

Fig. 2.5 The three reactors of a CLC system. [30]

### 2.2.1.3. The multi-reactors system

The configuration of this system was the repeat of two reactors system. For instance, there were 2 fuel reactors and 2 air reactors for combustion section. The configuration of reactors were parallel or series which it depended on the types of reactor. [30]

When classified the CLC types by the system of power production, there were 2 types; electro-chemical and thermo-mechanical.

## 2.2.2. The CLC using with a fuel cell

### 2.2.2.1. Solid oxide fuel cell (SOFC)/chemical looping-based system

Firstly, coal was gasified by gasification media;  $\text{CO}_2$  and  $\text{O}_2$  at gasifier reactor, when coal was used as the fuel of the system. The product of this process was syngas. After that, the syngas was introduced into the anode side of a SOFC. On the other hand, if the process was introduced by gaseous fuel; syngas or natural gas, the gaseous fuel would be introduced into the anode side of the SOFC without gasification step. The example of reactions at the anode were shown in Eqs. 2.3, 2.4 and 2.5, when the inlet gas including of  $\text{CH}_4$ ,  $\text{CO}$  and  $\text{H}_2$ . [32, 33] The main reaction at the anode was the oxidation reaction of  $\text{H}_2$  where  $\text{H}_2$  lost its electrons and it became  $\text{H}_2\text{O}$ .  $\text{H}_2\text{O}$  was used as a reactant and reacted with  $\text{CH}_4$  and  $\text{CO}$ . The products, consisting of  $\text{H}_2\text{O}$ ,  $\text{CO}$  and  $\text{CO}_2$ , and were sent to the fuel reactor. Next, the compressed air was introduced into the cathode side of the SOFC. There was

oxidation reaction of  $O_2$ , as shown in Eq. 2.6. After that the compressed air and the depleted air were introduced into air reactor [32, 33]

The products of this step were mixed with the air that was sent to the air reactor.

The discharge from the fuel and air reactors were sent to turbines for power production. The outlet streams from the turbines were used for heat recovery. The power was generated in 2 processes 1) SOFC and 2) turbines. The advantage of this process was the high thermal efficiency achievement, 72%. [34] The reason of high efficiency is that chemical energy was directly converted to electrical energy by the SOFC. In addition, the outlets of fuel and air reactors were used to produced power, as well. [35] The challenge of this process was the increased capacity for the power production. There was a pilot scale plant of a SOFC for  $H_2$  and power production at 500 kWe. [35] The configuration of the SOFC with CLC was shown in Fig. 2.6.

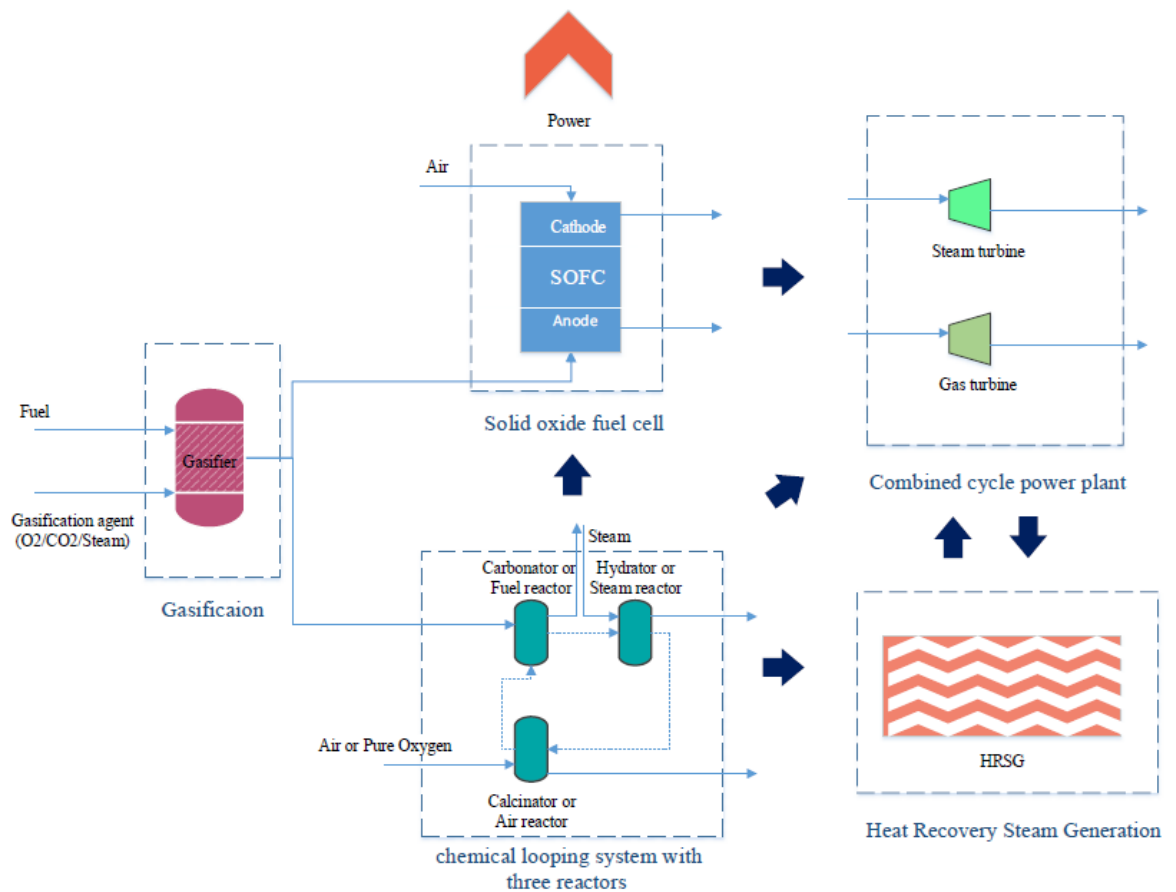

Fig. 2.6 The SOFC with CLC process. [30]

#### 2.2.2.2. Proton-exchange membrane fuel cells (PEMFC)/chemical looping-based system

The PEMFC was operated with the three reactors of a CLC system. [36] Syngas was treated the acid gas, sulfur compound and particulate matter. Firstly, fuel was reacted with oxygen carrier ( $M_yO_x$ ) in a fuel reactor. The products of the first step were  $CO_2$ ,  $H_2O$  and spent oxygen carrier ( $M_yO_{x-2}$ ). Next, steam was reacted with the spent oxygen carrier ( $M_yO_{x-2}$ ) in a steam reactor. The main product of this step was  $H_2$  and others were the excess  $H_2O$  and partially oxidized oxygen carrier ( $M_yO_{x-1}$ ).  $H_2$  from the steam reactor was purified. The CO might be found in low concentration (in PPM level). CO was eliminated by the oxidation process.  $CO_2$  was eliminated by pressure swing adsorption process (PSA). Next, the partially oxidized oxygen carrier ( $M_yO_{x-1}$ ) was reacted with the compressed air in air reactor. The products of this step

were oxygen carrier ( $M_yO_x$ ) and the excess air. The gaseous outlet of the air reactor was used for power production. The purified  $H_2$  from the steam reactor was introduced to the anode side of a PEMFC. The reaction at the anode was shown in Eq. 2.7. [37] Air was separated by an air separation unit. High purity of  $O_2$  was obtained and it was introduced into the cathode side of the PEMFC. The product of the cathode side was hot water. The reaction at the cathode was shown in Eq. 2.8. [37]

The net efficiency of a PEMFC was 43.6%. [36] The net efficiency of the PEMFC system was lower because the energy was highly consumed by ASU section. The economic analysis of Napoli et al. indicated that the net present value of the SOFC was higher than the PEMFC. [38] Even though, the investment cost of the SOFC was higher, the SOFC was preferable when it was operated for a long time (more than 6 years). [38]

### 2.2.3. The CLC for the utilization

Chemical looping processes were developed for other utilization such as chemical looping reforming (CLR), chemical looping hydrogen regeneration (CLHG), chemical looping air separation (CLAS) and chemical looping with oxygen uncoupling (CLOU). จุฬาลงกรณ์มหาวิทยาลัย

#### 2.2.3.1. Chemical looping reforming, CLR

The main product of a CLR is syngas. The essential property of an oxygen carrier in the CLR is the partially oxidation ability to obtain syngas. The product of fully oxidation is flue gas;  $CO_2$  and  $H_2O$ . The NiO is an oxygen carrier that is suitable for the CLR because of the strong catalytic properties. [39] In addition, the other oxygen carrier that is suitable for this process is  $CeO_2$  because it has high selectivity to produce syngas. [40] On the other hand, Fe-based, Mn-based and Cu-based oxygen carriers are the carriers that have low selectivity for syngas production. [41] The CLR principle is similar to the CLC principle. There are 2 main reactors; fuel reactor and air reactor, as shown in Fig. 2.7. Fuel is introduced into the fuel reactor and reacts with the oxygen carrier. The product of the fuel reactor was syngas; CO,  $H_2$ . By some

operation conditions, the  $\text{H}_2\text{O}$  and  $\text{CO}_2$  are introduced into the fuel reactor for steam reforming and  $\text{CO}_2$  reforming reaction. However, the steam reforming and  $\text{CO}_2$  reforming reactions are strong endothermic reactor. [42] The ratio of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  is limited, otherwise the external energy is required which it is the reason of low net efficiency of the system. The spent oxygen carrier is regenerated in the air reactor. The fuel is introduced into the system more than the air stream for fully oxidation prevention.

Fig. 2.7 The Flow diagram of CLR. [42]

### 2.2.3.2. Chemical looping hydrogen regeneration, CLHG

The CLHG is the three-reactor system. Accordingly, the principle of the CLHG and the three reactors of the chemical looping system are similar.

### 2.2.3.3. Chemical looping air separation, CLAS

The main product of a CLAS system is high purity  $\text{O}_2$ . [43] The CLAS process is usually applied with an oxy-fuel process and an integrated gasification combined cycle (IGCC). The CLAS process is included of 2 main reactors; an oxidation reactor and a reduction reactor, as shown in Fig. 2.8. The oxidation reaction occurs in an oxidation reactor as shown in Eq. 2.9. The spent oxygen carrier ( $\text{Me}_x\text{O}_{y-2}$ ) is oxidized by  $\text{O}_2$  in air to  $\text{Me}_x\text{O}_y$  which it is at the higher oxidation state. The reduction reaction takes place in a reduction reactor. The oxygen carrier ( $\text{Me}_x\text{O}_y$ ) releases  $\text{O}_2$  as shown in Eq. 2.10. It is at the lower oxidation state,  $\text{Me}_x\text{O}_{y-2}$ . The investigation of Shah

reported that  $Mn_2O_3/Mn_3O_4$ ,  $CuO/Cu_2O$ , and  $Co_3O_4/CoO$  were good candidates as oxygen carrier type for the CLAS process. [44]

Fig. 2.8 The flow diagram of CLAS and ICLAS. [44]

#### 2.2.3.4. Integrated chemical looping air separation, ICLAS

When a reduction medium is introduced into a reduction reactor of a CLAS system, the CLAS system becomes an integrated chemical looping air separation (ICLAS). When steam is used as the reduction medium, steam is the inert in the reduction reactor because it does not react with other species. [44] Even though, the inert does not directly affect the equilibrium reaction, the inert introduced into the reduction reactor increases the total pressure of the system. Then, the partial pressure of  $O_2$  in the reduction reactor decreases. Accordingly, the equilibrium is pushed into forward direction. The products of reduction reaction are  $O_2$  and  $H_2O$ . The  $O_2$  was purified by the condensation process. The ICLAS is applied to oxy-fuel combustion, as shown in Fig. 2.9. When the pure  $O_2$  from the reduction reactor is introduced into the combustion reactor, the temperature of the reactor is very high. Therefore,  $CO_2$  or recycled flue gas will be introduced into the combustion reaction for controlling combustion temperature. [43] The cost for  $O_2$  production by the CLAS process is lower than the cryogenic air separation unit (CASU).

Fig. 2.9 The oxy-combustion process for power production (Left), the oxy-combustion with ICLAS process for power production. [45]

### 2.2.3.5. Chemical looping with oxygen uncoupling, CLOU

The main reactors of a CLOU are air reactor and fuel reactor, as shown in Fig. 2.10. The oxygen carrier ( $Me_xO_{y-2}$ ) with low oxidation state reacts with  $O_2$  in the air, as shown in Eq. 2.11. The product from the air reactor is the oxygen carrier ( $Me_xO_y$ ) with higher oxidation state.  $Me_xO_y$  is transferred into the fuel reactor.  $O_2$  is released from  $Me_xO_y$  as shown in Eq. 2.12 and reacts with fuel in the fuel reactor, as shown in Eq. 2.13. [46] The CLOU concept enhanced the overall rate of the reaction, especially solid fuel. For solid fuel as coal, the rate determining step is the coal gasification. Nonetheless, when the coal is the fuel for CLOU process, the  $O_2$  releasing step is faster than the gasification. [47] Accordingly, the released  $O_2$  will react with the coal without the gasification step in system.

Fig. 2.10 The flow diagram of CLOU process. [46]

### 2.3. The oxygen carrier

Nickel-based oxygen carrier is also a good candidate for the oxygen carrier (OC) because of the high reactivity and high thermal stability. Therefore, the fuel conversion is completely combusted when methane is used as a fuel. [48] The reactivity of NiO is higher than CuO, Mn<sub>2</sub>O<sub>3</sub>, and Fe<sub>2</sub>O<sub>3</sub>. Iron-based OC is the most favorable OC because of its low cost and environment friendliness. Besides, iron-based OC was investigated as the oxygen carrier in many pilot scales. However, the power plant using iron-based OC had higher cost than those using nickel-based OC, due to its lower reactivity. The comparison of NiO and CuO expressed that the operation condition of NiO-based OC was higher than CuO-based OC. There was not sintering in the NiO process. The comparison of Ni-based OC and Mn-based OC expressed that Mn-based OC exhibited lower conversion when it reacted with methane. Accordingly, the nickel-based OC was still a good candidate for an oxygen carrier. Therefore, it was selected as an OC in this study because of its high reactivity and high thermal stability.

### 2.4. The section for power production

In previous content, the combustion section was mentioned. In this section, the unit for power production would be reviewed. There are 4 significant processes for

power production, including conventional steam cycle (SC), combined cycle (CC), steam injected gas turbine cycle (STIG) and humid turbine cycle (HAT).

#### 2.4.1. Conventional steam cycles, SC

The principle of this cycle is to extract energy from pressurized fluid and convert to power by a turbine. The process of steam cycle is shown in Fig. 2.11. The water was pumped to increase its pressure before feeding into a boiler. Water was boiled to steam in the boiler. The outlet steam from the boiler was high pressure and temperature. Then, the steam was used for power production by expanding in the turbine.

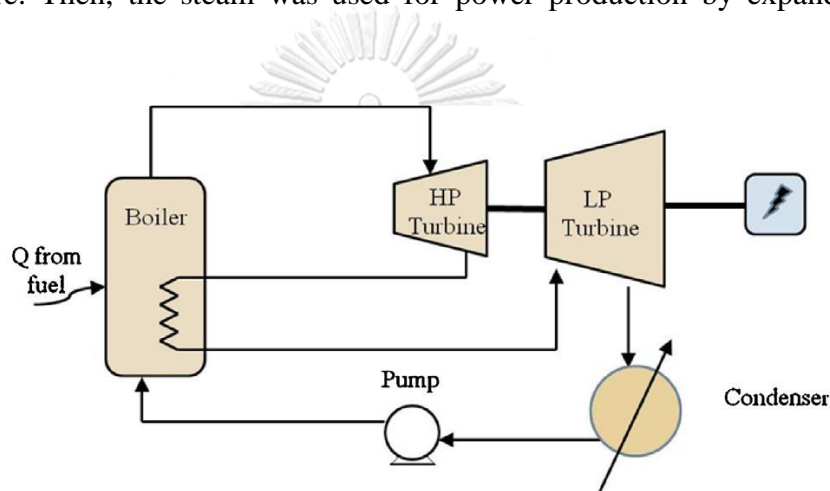

Fig. 2.11 Steam cycle [49]

#### 2.4.2. Combined cycle, CC

The process of combined cycle is shown in Fig. 2.12. The steam is generated in a heat recovery steam generator (HRSG). Steam at high pressure and temperature is used to produce the power by a steam turbine which is similar to steam cycle. Nonetheless, the combined cycle has the supplementary section from steam cycle. The combined cycle also includes the combustion section. In the combustion section, air is compressed to obtain high pressure by a compressor. The fuel is combusted with the compressed air in combustion section. The flue gas from combustion section has high pressure and temperature. The flue gas is introduced into a gas turbine for power production. The remaining heat of flue gas after power production is used to preheat water at HRSG.

Fig. 2.12 Combined cycle [49]

### 2.4.3. Steam injected gas turbine cycle, STIG cycle

The STIG is similar to a combined cycle that the combustion section is included. The flow diagram of a STIG is shown in Fig. 2.13. Air is compressed by a compressor to increase its pressure. Water is pumped into a HRSG unit to produce superheated steam and introduce into a combustion reactor to combust with the compressed air and fuel. The product from the combustion reactor is flue gas which is sent to a turbine for power production. The superheated steam generation step includes 3 main processes; economizer, evaporator and superheater. [47] Water is pumped into an economizer for preheating. Then, it is evaporated to eliminate the condensed liquid water. The saturated steam is introduced into a superheater to increase the energy of the steam and obtain superheated steam. However, the amount of steam was limited by the heat at the HRSG unit.[50] The benefit of the superheated steam is 1) the NO<sub>x</sub> reduction in the combustion section by decreasing the temperature in the reactor and 2) the increase of power production by increasing mass flowrate inlet to the turbine. In addition, the enthalpy of superheated steam is higher than that of air at the same temperature. Accordingly, the power production of this process was increased by superheated steam injection through the combustion section, leading to the increase of total efficiency of the power production process, as well.

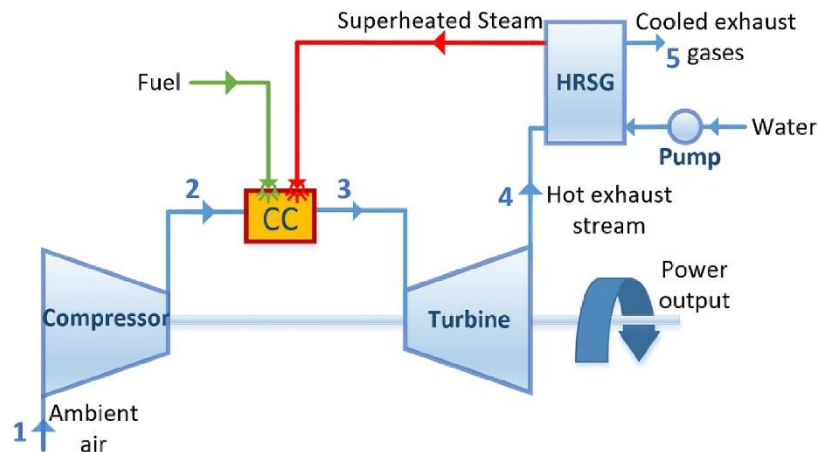

Fig. 2.13 STIG cycle [47]

#### 2.4.4. Humid air turbine cycle, HAT cycle

The humid air turbine (HAT) cycle is the power production section that aims to offer higher thermal efficiency with a low-investment cost [51]. The flow diagram of a HAT cycle is shown in Fig. 2.14. This cycle is similar to the STIG that uses superheated steam in the combustion section. Nonetheless, the HAT cycle has the supplementary section from the STIG cycle. The HAT cycle includes the air compression section which is divided to multi-stage compressor for reducing compression work. The 2 main processes of the HAT cycle are the multi-stage compressor and the humidifier. The multi-stage compressor has the inter-cooler or heat exchanger installed between each stage of the compressor.

Air is compressed in the first stage of the compressor. The compressed air has higher pressure and temperature. Then the compressed air is cooled by the intercooler and fed to next compressor. Due to lower temperature of the compressed air, the work required by the air compressor becomes less. The heat from the compressor was transferred to the cooling water at the inter-cooler. Air was alternately compressed and reduced heat, until the last stage of compressor. Then, the compressed air and the hot water were introduced to a humidifier. The hot water is evaporated into the air until it reaches the saturated condition. [52] Therefore, the humidifier was the unit that eliminated the condensed liquid water and produced the humid air. Then, the humid air is preheated by the recuperation reactor. The humid air is fed into the

combustion reactor. The flue gas is at high pressure and temperature and it is sent to a turbine for power production.

The benefits of a HAT cycle include 1) the increase of power production by increasing the mass of working fluid passed through a turbine and 2) the increase of net power production by reducing the turbine work consumption. This cycle is the best gas turbine cycle. [52] Moises et. al. reported the comparison of 3 types of power production unit of a CLC process which was comprised of SC, STIG cycle and HAT cycle. The study indicated that the net plant efficiency of CLC-SC, CLC-STIG and CLC-HAT were 50.25%, 50.49% and 56.08%, respectively. Consequently, the HAT cycle was the best power production cycle. [49]

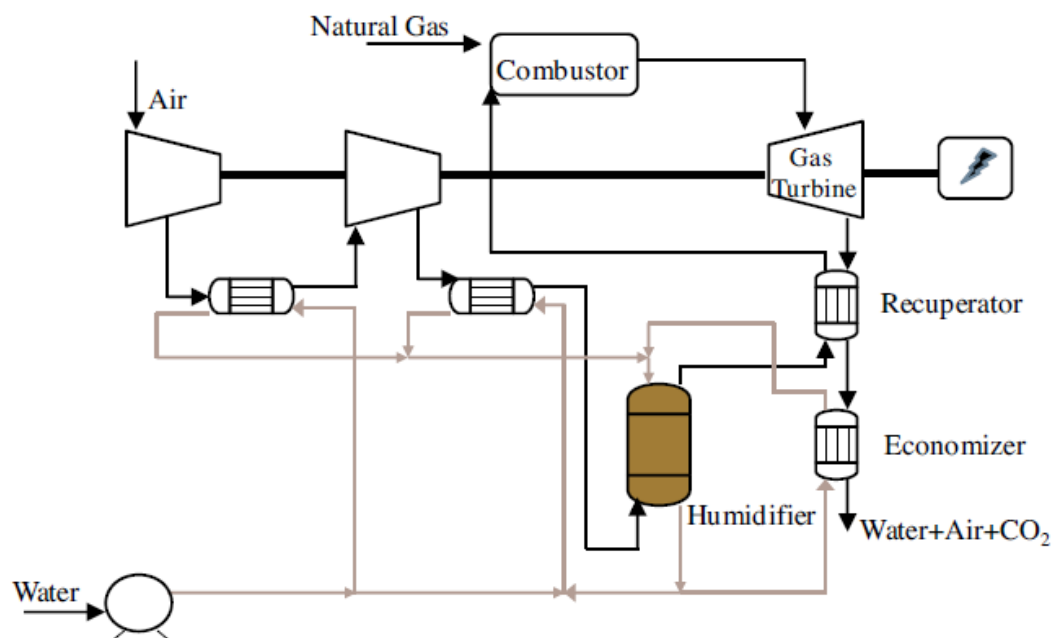

Fig. 2.14 HAT cycle [49]

## 2.5. Aspen plus program

The advanced system for process engineering (ASPEN) program was the powerful tool and extensive usability for the virtual chemical processes. This program has arisen by the cooperation of Massachusetts Institute of Technology (MIT) and US Department of Energy since 1981. The aspen plus program has been used to simulate the whole process at steady state. [53] This software consists of the various thermodynamic properties which is suitable for a specific process. The used

components in the process are customized. Therefore, it could be used for various reactants and products. The most advantage is process optimization with high accuracy. The optimum operation condition of the process could provide high material and energy utilization.

The guideline for simulation by aspen plus is as followed. Firstly, the problem of a case study for simulation was determined. Then, the given conditions of the simulation case such as components, compositions, and thermodynamic properties were specified. After that, each unit operation was selected and connected with each other to represent the simulated process. Eventually, the connected unit operations were simulated until the result was validated or the simulation was completed, as shown in Fig. 2.15.

Fig. 2.15 The process to achieve the ASPEN plus simulation [54]

## 2.6. The computational fluid dynamic.

Computational fluid dynamics (CFD) is used to investigate the fluid flow behavior by the numerical analysis. [55] CFD simulation is an efficient tool to explore the detailed local data and multiscale flow structures in a fluidized bed reactor. [56] CFD simulation is a suitably engineering tool that could build the understanding of the complex behavior of gas-solid flow within the CLC reactor. [57] The gas-solid flow model is divided into 2 methods;

### 2.6.1. Eulerian-Eulerian method

- Gas and solid phases (carrier phase) are determined as the continuous phase.
- The advantage of this method is that it uses lower computational resource because the effects of particle size distribution is neglected.

### 2.6.2. Eulerian-Lagrangian method

- Gas phase is determined as the continuous phase. Solid phase is determined as particle by particle.
- The advantage of this method is the detailed data of particle behavior.

The guideline for implementing CFD simulation is shown in Fig. 2.16. The first step, the problem is identified. The second step, the geometry of equipment or object that will be investigated to fluid behavior is created and set up the solver with suitable conditions. The third step, the simulation case is calculated with numerical method until it converges. The final step, the result is interpreted. When the result is not reasonable, the model will be adjusted until it is validated with the experimental data. Ansys fluent is the commercial simulation program that is the most powerful tool, well-validated physical model and high accuracy result. [58]

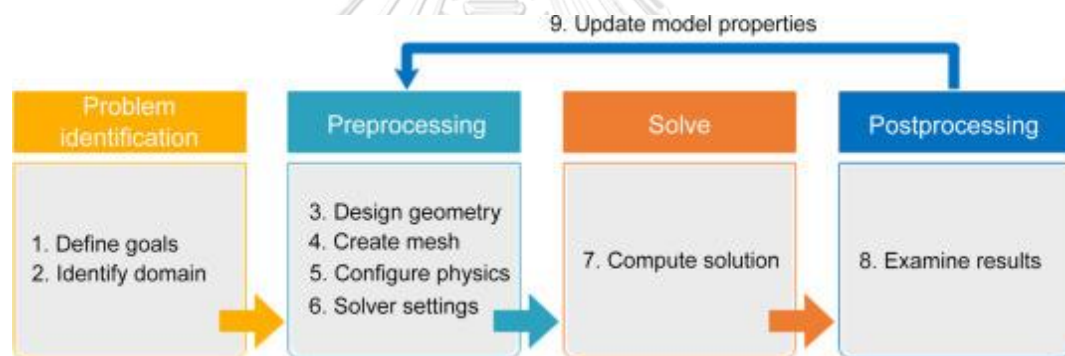

Fig. 2.16 The process to achieve the CFD simulation [58]

### 2.7. Economic analysis

The outcome of economic analysis indicated the investment cost, operation cost and the project benefit. [59] It was also used for the best-case comparison in decision making.

The step for economic analysis in this study was followed. [60, 61] Firstly, the problem description of a case study for economic analysis was specified. Then, equipment cost, fix capital cost (FCI), total capital cost (TCI), cost of manufacturing without depreciation ( $COM_d$ ) depreciation, sale price, total annual income and expenses and indicators of economics were calculated respectively, as shown in Fig. 2.17.

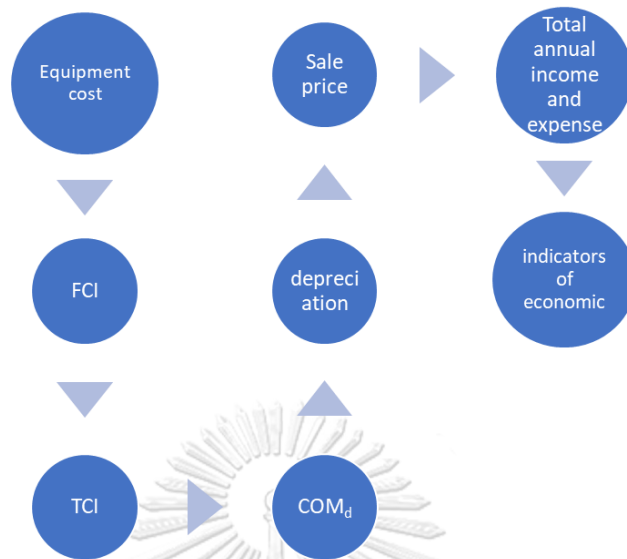

Fig. 2.17 The process to achieve the economic analysis [60, 61]

### 2.7.1. Equipment cost

The equipment cost was obtained from the economic analysis data provided by aspen plus program or the cost estimation from the plant design and economics for chemical engineer's book. [60]

### 2.7.2. Fixed capital investment cost, FCI

FCI consists of direct cost and indirect cost. The main part of the direct cost includes purchased equipment and service facilities costs. The main part of the indirect cost was contingency. FCI was relied on the Table 17 of plant design and economics for chemical engineer's book which represented the details of the FCI composition and the ratio factors for estimating capital-investment items which based on delivered equipment cost for solid and fluid processes. [60] In this study, the details of the FCI composition for the solid and fluid processes after normalized is shown in Table 2.1.

**Table 2.1** The components of FCI

Component	%FCI
<b>Direct cost</b>	
Purchased equipment	22.35
Purchased-equipment installation	8.72
Instrumentation and controls (installed)	2.68
Piping (installed)	6.93
Electrical system (installed)	2.23
Buildings (including services)	6.48
Yard improvements	2.23
Service facilities (installed)	12.29
Land	1.34
<b>Indirect cost</b>	
Engineering and supervision	7.15
Construction expense	7.60
Contractor's fee (about 5% of direct and indirect plant cost)	5.00
Contingency (about 10% of direct and indirect plant cost)	15.00

### 2.7.3. Total capital investment cost, TCI

The total capital investment cost (TCI) is composed of fixed capital cost (FCI) and working capital cost (WC). The 85% of TCI is FCI and 15% of TCI is WC, as shown in Fig. 2.18. The total capital cost is the annual cost at the beginning of the plant operation.

Fig. 2.18 The component of TCI.

#### 2.7.4. The operation and maintenance costs [61]

$$COM_d = 0.180FCI + 2.735C_{OL} + 1.235(C_U + C_{WT} + C_{RM}) \quad (2.14)$$

$COM_d$  = cost of manufacturing without depreciation

$C_{OL}$  = cost of administrative, supervisory or laboratory

$C_U$  = cost of utility

$C_{WT}$  = cost of waste material

$C_{RM}$  = cost of raw material

#### 2.7.5. The cost of administration, supervisor or laboratory

The calculation of this cost is based on the number of operators and the unit operations that involved with particulate handling.

$N_{NP}$  = Total unit of compressor, tower, heat exchanger and reactor

$$N_{OL} = \text{Number of operators per shift} = (6.29 + 31.7P^2 + 0.23N_{NP})^{0.5} \quad (2.15)$$

$P$  = Number of solid process

Total number of labors (persons) = Shifts per day x  $N_{OL}$

Total labor cost = Cost of operating labor cost x Total number of labors

#### 2.7.6. Depreciation cost

The depreciation cost is the decrease of asset cost. There are several types of depreciation calculation; straight-line, double declining, units of production and sum of years digits.

### 2.7.7. The significant indicator for economic analysis

#### 2.7.7.1. Net present value (NPV)

NPV indicates the total annual cash flow at the present viewpoint. NPV is calculated by using Eq. 2.16.

$$NPV = \sum_{n=0}^M \frac{CF_n}{(1+I)^n} \quad (2.16)$$

When CF = cash flow

n = each period

M = the end of plant operation

I = discount rate

#### 2.7.7.2. Internal rate of return (IRR)

IRR indicates the return rate when NPV is zero. IRR is calculated by using Eq. 2.17.

$$\sum_{n=0}^M \frac{CF_n}{(1+IRR)^n} = NPV = 0 \quad (2.17)$$

#### 2.7.7.3. Breakeven point

Breakeven point indicates the point that the accumulated present value is equal to zero.

#### 2.7.7.4. Payback period

Payback period indicates the period that the accumulated present value equal zero.

### 2.8. Sustainability evaluation

The sustainability evaluation has been proposed by Odum [62] which it is energy analysis. The emergy is “the available energy of one kind previously used up directly and indirectly to make a product or service”. Every material, energy, monetary, and manpower are counted in this analysis which it will transform into the same unit. The analysis combines ecology concepts into energy calculations to measure the direct and indirect inputs along with the transformation processes. This

evaluation procedure covers all the energy-related to the system, including the material, energy, monetary, and manpower, and then converts them all into solar energy. In an energy view, 1 joule of electricity is equal to 1 joule of thermal energy. However, in terms of energy analysis, 1 joule of electricity represents  $8.05\text{E}+04$  solar equivalent joules (sej), whereas 1 joule of thermal energy can represent different sej values depending on the fuel used. For example, 1 joule of thermal energy obtained from coal, methane, or wood would be  $1.69\text{E}+05$  sej/J,  $1.70\text{E}+05$  sej/J, or  $6.72\text{E}+04$  sej/J [62], respectively. The solar energy that was used to produce 1 joule of energy was the UEV. The UEV was calculated from the total solar energy utilized by the process to produce the product divided by the energy of the product. However, the accuracy of the energy analysis depended on the assumption and the database of the UEV. The distinct advantage of energy analysis was the consideration of types of resources and the sources of resources that are different from other analyses. The summary of energy analysis is the analysis that converts of material, energy, cost, and all data that involve the process into a solar energy form. When the procedure was based on solar energy, it represented all solar energy that was used to perform the resource. Accordingly, this analysis expresses the genuine value of the resource. With the procedure of energy analysis, the result reveals the self-sufficiency which other methods could not explain. This analysis result would reveal both economic and environmental impact by significant energy indicator which included of 1) unit energy value (UEV), 2) environmental loading ratio (ELR), 3) energy yield ratio (EYR), and 4) energy sustainability index (ESI).

### **2.8.1. Unit energy values, UEV**

UEV is a transform factor which it was calculated from the ratio between the total energy and energy flow product and service as shown in Eq. 2.18. In good case, UEV is low. The low UEV indicate the low total energy flow for product one unit of product. [62] This transformity make different between economic and energy analysis. Economic take everything into account by price which it is indicated by the human need. However, the energy flow is indicated by all the solar energy that used to produce the products, energy or service. Accordingly, the energy analysis will

represent more reasonable result than economic. In addition, the UEV is used to transform all of energy stream into one form of solar energy (sej), as well.

$$UEVs = \frac{\text{Total Energy flow}}{\text{Energy flow, Products flow, Service}} \quad (2.18)$$

### 2.8.2. Environmental loading ratio, ELR

ELR is the environmental loading ratio which it represents the loading of the process to the environment as shown in Eq. 2.19. In good case, ELR should low. When ELR is close to 2, it is low environmental loading. When ELR between 3-10, it is moderate level of environmental loading. Finally, when ELR is more than 10, the environmental loading is high level. [63]

$$ELR = \frac{N+F}{R} \quad (2.19)$$

N = local non- renewable resource; natural gas.

R= local renewable resource; water, air.

F = expense cost, external goods, Ni, Na<sub>2</sub>CO<sub>3</sub>, Al<sub>2</sub>O<sub>3</sub>, equipment, labor cost.

### 2.8.3. Emery yield ratio, EYR

EYR is emery yield ratio which it indicates competitive ability in economic and the stability of process. EYR is calculated from the total emery flow which divided by the emery of expense goods (F), as shown in Eq. 2.20. In good case, EYR is high. The reason of high EYR is low F. It represents that the process is hardly relied on external resource. When the process relies on internal resource, the process will high stability which it is highly competitive ability in economic, as well. In good case, EYR is high but, in worst case, EYR is equal to 1. Moreover, when EYR is lower than 2, it indicates that the process is not suitable to be an energy source by the study of Ulgiati and Brown. [29]

$$EYR = \frac{\text{Total emery}}{\text{External resources}} = \frac{R+N+F}{F+L} \quad (2.20)$$

#### 2.8.4. Emergy sustainability index, ESI

ESI is emergy sustainability index which it indicates the sustainability of the process. It is calculated from the ratio of EYR to ELR, as shown in Eq. 2.21. It is the ratio of profit to the loading of the environment. When ESI is lower than 1, the process is not long-term sustainability. When ESI is 1-5, the process is medium sustainability. Finally, when ESI is higher than 5, the process is long term sustainability.

$$ESI = \frac{EYR}{ELR} \quad (2.21)$$

### 2.9. The literature reviews

#### 2.9.1. The investigation of the operation conditions

There were many researches that studied the operating conditions to improve the system efficiency. The thermal efficiency of the CLC was higher than the conventional combustion with CO<sub>2</sub> capture process because it was not only heat generator unit but also inherent CO<sub>2</sub> separator unit. [34, 64, 65] The countercurrent gas–solid flow pattern, low moisture content of feeding biomass, temperature of fuel reactor (>600 °C), low pressure (<40 atm) in the fuel reactor increased the conversion of oxygen carrier. [4] The five parameters for operating the reactors were studied; temperature inlet of air and fuel, temperature of reactors, temperature inlet to turbine, temperature outlet from reactors and pressure of reactor. [28] The high temperature and pressure led to high efficiency of the system. Olaleye and Wang [66] studied a CLC with HAT cycle for power production which reached 57% thermal efficiency. They investigated four effects including 1) effect of humidified air to fuel ratio on concentration products, 2) effect of fuel flow on NiO conversion, 3) effect on temperature inlet of fuel to thermal efficiency, and 4) effect of inlet and outlet temperature of air reactor on thermal efficiency. The use of supercritical steam for power production also increased the net efficiency of natural gas [67] to 43.11% because this steam boiler was operated in high pressure operating condition (240 bar). [67] The change of compression ratios showed that there was an optimum point for the operation. Beyond that point the efficiency would decrease. [27] Furthermore, there were other groups of research works focusing on modification the system to improve the system efficiency. The modified power generation system called CLSA, which

had a multistage of compressors increased the thermal efficiency to 55.1% [68]. Ibrahim studied types of the CLC and types of oxygen carriers for power generation [49]. The results indicated that the thermal efficiency of the CLC with HAT cycle by using Ni as an oxygen carrier was 56.08%. The CLC with HAT cycle for power production was investigated. Olaleye and Wang [69] studied the effect of fuel inlet temperature, inlet and outlet temperature of air reactor, effect of humid air and Ni flow rate, and effect of air to oxygen carrier ratio on thermal efficiency. Nevertheless, it could not explain the interaction between each effect. In fact, all variables affected to each other and could not be separately investigated. The  $2^k$  factorial would be the methodology to explain all of the main and interaction effects on the system. Fun et al. [70, 71] studied a CLC operated with combined cooling, heating and power production (CCHP-CLC). The obtained thermal efficiency of the process was 58.20% in summer and 60.34% in winter. This process was suitable for some countries that had enough different temperatures by season change. Other combination process, the CLC with solid oxide fuel cells (SOFCs) gained very high thermal efficiency that was 63-70% [34] because chemical energy from fuel was directly converted to electricity. SOEC was solid oxide electrolysis that had high efficiency for  $H_2$  production. [72] The combination of the SOEC and CLC obtained 56% efficiency [9]. Power and  $H_2$  were produced from this process at the same time. However, the result was based on the operation in a lab scale equipment only.

### **2.9.2. The investigation of the hydrodynamics.**

There were many researches that studied the operating conditions to improve the hydrodynamics. For the latest investigation of a fluidized bed reactor for the CLC process, the study of cold flow models which the reactions were not included in calculation was highly investigated. The solid circulation rate (SCR) was examined in a cold flow model by the CFD-DEM (dynamics-discrete element) in the study of Peng et al. [73] The result of Peng et. al. demonstrated that SCR was strongly impacted to the conversion of oxygen carrier, the size of reactor and the heat transfer between air and fuel reactor which it was transferred by the oxygen carrier. Yin et al. researched the bubbling regime in fuel reactor which the fluidized bed reactor was used for their study. [74] The result of Yin et. al. demonstrated that the high  $CO_2$

concentration was obtained when the pressure in the fuel reactor was increased. In addition, the fuel feeding position was studied. Yin et. al. suggested that the better hydrodynamic behavior was achieved when fuel was introduced at the lower feeding position. The CLC reactor in pilot scale at 1 MW<sub>th</sub> was investigated in the three dimensional system by May et al. [75] The simulation was validated with the experimental data. The result demonstrated that the temperature result from the simulation and the experimental data was insignificant different. The deviation of temperature might be the result of the assumption in the simulation. The result of Merrett and Whitty demonstrated that the carbon conversion was significantly increased in the chemical looping with oxygen uncoupling process (CLOU) because of temperature. [76] In this study, the DCFBR was performed in simulation investigation.

The suitable operation condition provided the high conversion in reactor. Furthermore, the configuration of reactor was the important part for enhancing the conversion reaction, as well. Chen et al. investigated the hydrodynamics within the dual circulating fluidized bed reactor ( DCFBR) . The DCFBR enhanced the conversion of the fuel reactor. [57] The height of fuel reactor was higher than air reactor. Therefore, the residence time and conversion within fuel reactor was increased when DCFBR was selected as the reactor. The loop seal was the critical part of the DCFBR. The loop seal was the connecting part between downer and riser. It was contained with solid return from the cyclone and prevented the reverse flow of gas to the downer section.

### **2.9.3. The investigation of Energy.**

The development of power production is also important for the industrial and commercial sectors. Hence, it is crucial to evaluate the environmental impact of any power production processes before deciding on constructing a new power plant. The life cycle assessment (LCA) is the most widely used tool for environmental assessment. [77, 78] A previous LCA study of a CLC indicated that the CLC produces a lower environmental impact than a conventional power production process. [79] The limitation of the LCA is that the method cannot ascertain the economics and long term sustainability of the process [80], nor can it quantify the social cost and the impact of

the environment [81]. Several issues related to conventional analysis tools include: (i) that the mixing units, such as the weight, heat capacity, volume, power, and cost, cannot be exactly compared; and (ii) the resources, products, and processes, that cannot be evaluated in a price form, are not quantified. [82]

The emergy analysis was used to assess the performance of the process in various fields such as agricultural system, energy production, city development, etc. The evaluation from the emergy analysis represented the deep information which deserved for further development. [83] The best-case study exhibited the net benefit to society and low environmental loading. In the study of Yazdani et. al., the emergy analysis was used to evaluate the 2 power plants which used the different fuel types; natural gas (NG) and municipal solid waste (MSW). The result indicated that the ESI of the MSW cases was higher because the percent of renewability (PR) of MSW case was higher. [84] Sha and Hurme investigated the cogeneration process for heat and power production, the study indicated that the emergy analysis could be applied for evaluating efficiently the power plants in a sustainable viewpoint. The sustainability index of biomass based was higher than coal based in 1.5 times. [85] The cogeneration was a 20-35% reduction of the emergy in the production process when compared to the individual production process. In the study of Zhang et. al., the emergy analysis was used to evaluate the waste heat power generation process. [86] The waste heat utilization was the one approach to increase the efficiency of the system. The power was generated by the organic Rankine cycle (ORC). The result indicated that the ESI of ORC power was lower than wind, hydro and geothermal power plant. However, the ESI of ORC power plant was higher than fossil fuel power plant. The EYR of ORC was the highest of the six-power plants (wind, geothermal, hydroelectric, methane-fired power plant, oil-fired plant and coal-fired power plant) because the purchase from the ORC case was the lowest. In the study of Wang et. al., the process for power production was evaluated by emergy analysis. [87] The 3 processes were included of 1) pulverized coal-fire with combined heat and power plant, 2) coal-fired and pressurized fluidized bed combustion with combined cycle, and 3) coal-fired with integrated gasification combined cycle. The result indicated that EYR of case 3 and case 2 were higher than case 1. With this reason, ESI of case 3 was the highest. In the study of Ulgiati et. al., the process for power production was

evaluated by emergy analysis, especially the cycle for power production. [88] The steam cycle and the combined cycle were compared. The emergy analysis indicated that the electrical transformity of combine cycle ( $1.905E+05$  seJ/J) was lower than steam cycle ( $3.15E+05$  seJ/J). It represented that the combined cycle required the lower total resources. When the main product was changed from only electricity to heat and electricity, the transformity of 2 cases was highly reduced. The co-generated product transformity of combine cycle and steam cycle were  $1.56E+05$  and  $1.73E+05$  seJ/J, respectively. The result indicated that the co-products production and the optimal resources were the key to obtain the sustainable development.

### **Chapter 3**

#### **The methodology of this research**

The research was divided into three sections: (1) The process efficiency improvement for the power production using a CLC as the key thermal engine had been explored. (2) The hydrodynamics of the CLC was investigated. (3) The sustainability of the process was evaluated.

The operation conditions of a CLC process with the HAT cycle for power production was systematically investigated by  $3^k$  factorial experimental design, in chapter 4. The four input parameters and the four responses provided the optimum operation condition that reached the highest thermal efficiency.

The hydrodynamic behavior of the CLC reactor was investigated in chapter 5. The dual circulating fluidized bed reactor was selected to be studied. The suitable hydrodynamic behavior would provide high performance of the CLC process. In this section, there were two types of fuel; solid fuel and gaseous fuel. For gaseous fuel, the operation conditions from chapter 4 were used to prove whether the operation condition was suitable. The outcomes of this section were the operation condition and the reactor size.

In chapter 6, there were three types of analysis including 1) thermal efficiency, 2) economic analysis and 3) the sustainability analysis, for selecting the best-case study. The effects of combustion types, CO<sub>2</sub> capture efficiency, carbon tax and HAT cycle were included in this section which provided six case studies. The equipment and operation costs from chapter 4 were used in economic and sustainability analyses. In addition, the CLC reactor size was calculated from chapter 5, as shown in Fig. 3.1. The outcomes of this section were the viewpoint of different analyses on the process and the suggestion for the CLC process improvement.

Fig. 3.1.1 The flow diagram that represents the relationship among chapter 4, 5 and 6

### **3.1 The methodology of chapter 4; the investigation of operating parameters of a CLC with HAT cycle process for power production**

#### **3.1.1 The research gaps**

The limitations of previous studies of the CLC study are the individual investigation of each parameter. However, all parameters in the system have interacted with each other and they could not be studied separately. In this study, the  $3^k$  factorial design was used for examining the effects of these parameters systematically and identify their effects and interaction with the minimum treatment number. For this part, four independent input variables are the pressure of the air reactor, the number of stages of air compressors, methods of air compression operation and airflow rate. Four responses of the process consist of thermal efficiency, power production from air reactor, work of air compressors and air compressor discharge temperature. It is the first time that the operating parameters of the HAT cycle and those of a CLC process were systematically investigated. The HAT cycle is composed of the multi-stage compressors, heat exchangers for intercooler between compressors and a turbine. Accordingly, the operation of the HAT cycle is directly relating to compressors and turbine workloads, which affect on power production of the system. The  $3^k$  factorial result could reveal the main factors, the interaction and curvature interaction among operation parameters on the thermal efficiency of the system.

#### **3.1.2 Objective**

To study the effects of operating conditions on the power production of the chemical looping combustion process with the HAT cycle.

### 3.1.3 Methodology

#### 3.1.3.1 Process description

Fig. 3.1.2 The flowchart of CLC for power production system and flow chart of preheating section

The CLC process with the HAT cycle was simulated for evaluating the system efficiency by Aspen plus simulator. In this study, it was the gas and solid system because natural gas was used as a fuel and NiO on  $Al_2O_3$  was used as the oxygen carrier. The Peng-Robinson-Boston-Mathias (PR-BM) was the thermodynamics properties suitable for simulating the solid and fluid process. The PR-BM was the modified equation of state with a high explicit prediction for multiphase system [89] and the solid-gas process. [49] The CLC process with the HAT cycle was complete by Petriz-Prieto [49] and the thermal efficiency of their system was 55.88%. This developed process was including of a CLC process for heat production and the HAT

cycle for power production. There were two reactors in the CLC section, air reactor (AR-101) and fuel reactor (FR-101), which was operated as a cycle as shown in Fig. 3.1.2. The multi-stages compressor was a part of the HAT cycle for decreasing the workload of the compressors. The heat exchangers were installed between the compressor stages. The cooling water was fed into a heat exchanger for releasing heat in the compressed air. Then the compressed air was sent to the next compressor stage. Its workload was reduced. For the three-stage compressors, air would be compressed at C-101; it was cooled down at HX-101. The compressed air was sent to the next compressor, C-102, and next heat exchanger, HX-102. Finally, the compressed air would be transferred to the last stage compressor, C-103. For other number stages of compressors, air would be alternately introduced into compressors and heat exchangers until the last stage of the compressor. The compressed air and cooling water were fed into the HAT cycle; after that, it was preheated at the preheating section. Water was preheated until it was vaporized. The stream was combined with compressed air. Then the humid air was fed into the air reactor. The Ni metal and  $\text{Al}_2\text{O}_3$  supporter were fed into the air reactor (AR-101) for reacting with the compressed air and producing oxygen carrier: NiO. The ratio of Ni to  $\text{Al}_2\text{O}_3$  was 0.25/0.75 by a mole at  $1350^\circ\text{C}$ . The NiO was separated from excess air by a cyclone (CYC-101). The excess air with high temperature and high pressure was introduced to a turbine (TURB-101) for power production. The natural gas was preheated at the preheating section. After that, it was introduced into a fuel reactor (FR-101) for reacting with NiO. The spent metal oxide was separated from gas products by a cyclone (CYC-102). The gas outlet from the fuel reactor (FR-101) was sent to a turbine (TUR-102) for power production. The gas products from the fuel reactor consisted of water and  $\text{CO}_2$ , which water was condensed from flue gas by a condenser, CSR-101. The solid product from the fuel reactor was Ni, which was sent to the air reactor (AR-101) for regeneration. The metal in the system was recycled in the CLC process. The outflow from the cyclone was introduced to the preheating section for heat recovery. Air and water were preheated by the high temperature streams from TUR-101 by HXA-107, HXA-106, HXF-102, HXA-105, HXA-104, HXA-103, HXA-102 and HXF-101, respectively. The high temperature stream from

TUR-102 by HXF-105, HXA-108, HXF-104, HXF-103 and HXA-101, respectively, preheated natural gas.

### 3.1.3.2 Experimental design

The CLC with the HAT cycle process was investigated to improve thermal efficiency when using natural gas. The condition of natural was shown in Table 3.1.1.

**Table 3.1.1** Aspen Plus models and operating parameters

Thermodynamics properties		PR-BM
Ni/Al <sub>2</sub> O <sub>3</sub>	Flow rate (kmol/hr)	48658.04
	Mass fraction (-) [47]	0.16/0.84
	Temperature (°C)	1350
	Pressure (atm)	1
Water	Mass fraction in humid air by weight	0.14-0.18
Natural gas	Flow rate (kg/s)	14.2
	Temperature (°C)	25
	Pressure (atm)	20
Composition of natural gas	Nitrogen	0.28
	Carbon dioxide	0.70
	Methane	89.51
	Ethane	5.92
	Propane	2.36
	n-Butane	0.40
	i-Butane	0.56
	n-Pentane	0.08
	i-Pentane	0.13
	Hexane	0.06

The factorial experimental design was selected to investigate the effects of all parameters on the process performance with the minimum case studies. [90] The 3<sup>k</sup> factorial experimental design was implemented to identify the operating parameters that led to optimum thermal efficiency. Since pressure significantly affected the efficiency system [49, 91, 92], it was included as a parameter to be evaluated. In this study, there were four parameters: the pressure of the air reactor, the number of air compressor stages, the Method of air compression and airflow rate. The four responses to be observed are: thermal efficiency consists of thermal efficiency, power production from air reactor, work of air compressors and air compressor discharge

temperature. In summary, there were 81 cases in total to be simulated and evaluated the outputs. The values of these four input variables which were used in the study were shown in Table 3.1.2.

**Table 3.1.2** The values of four parameters that was conducted in  $3^k$  factorial experiment.

Variable	Name	Units	Low value	Middle value	High value
A	The pressure of air reactor	atm	5	10	15
B	Number of compressors	Number	3	5	7
C	Air compression method	-	Method 1	Method 2	Method 3
D	Air flow rate	kmol/hr	58000	59500	61000

### 3.1.3.3 Thermal efficiency

Thermal efficiency indicated the efficiency of the fuel used to produce electricity in the system. It can be expressed as the ratio of net power production to the thermal energy of the fuel, as shown in Eq. 3.1. The net power production was calculated from the power production from air and fuel reactors which was subtracted by the power consumption from compressors and pump. The thermal energy of the fuel was calculated from the lower heating value of natural gas.

$$\text{Thermal efficiency (\%)} = \frac{P_{AR} + P_{FR} - P_C - P_P}{LHV_{NG}} \times 100 \quad (3.1)$$

Note that;

$P_{AR}$  = power production from air reactor (kW)

$P_{FR}$  = power production from fuel reactor (kW)

$P_C$  = power consumption from air compressors (kW)

$P_P$  = power consumption from pump (kW)

LHV = lower heating value (kW)

NG = natural gas

### 3.1.3.4 Method of air compression

The operation of multi-stage compressors with a different compression ratio of each compressor has never been studied before. In a previous study, the compression ratio of multi-stage compressors was fixed to be equal in every stage [93, 94]. The significance of this operation and the effect on four responses were assessed in this study. Because the HAT cycle uses many compressors, the compression ratio became a significant parameter of the system. The compression ratio is the ratio of the outlet stream pressure to the input stream pressure, as shown in Eq. 3.2.

$$\text{Compression ratio} = \frac{\text{Pressure outlet}}{\text{Pressure inlet}} \quad (3.2)$$

The compression ratio directly affects its compressor workload, discharge temperature, and the temperature of the air reactor. When a high compression ratio was used, the pressure and temperature outlet of the compressor would be high, and the workload of the compressor would also be high. Thus, the compression ratio would be kept less than 3 to avoid too much workload and too high temperature outlet [95, 96]. Some compression ratio of the compressor in this study was higher than three and the temperature of the outlet stream is high. The heat of the outlet stream would be used in the preheat section. Typically, the high compression ratio consumes higher work in multi-stage compressors. There were many alternatives for setting up

operation methods. In this study, three operational methods were being studied their effects on the four responses.

Method 1: The outlet pressure of the first stage compressor is 65% of the total pressure of the air reactor. The rest of the compressors has an equal compression ratio by sharing of 35% of total pressure.

Method 2: All compressors in the system use an equal compression ratio.

Method 3: The outlet pressure of the last stage compressor is 65% of the total pressure of the air reactor. The rest of the compressors has an equal compression ratio by sharing of 35% of total pressure.

The compression operation for 5 compressors and 10 atm was shown in Table 3.1.3

**Table 3.1.3** The compression ratio of all method of compression.

	Compression ratios				
	stage 1	stage 2	stage 3	stage 4	stage 5
Method 1	6.5	1.1	1.1	1.1	1.1
Method 2	1.6	1.6	1.6	1.6	1.6
Method 3	1.1	1.1	1.1	1.1	6.5

## **3.2. The methodology of chapter 5; hydrodynamic behavior of chemical looping combustion**

### **3.2.1 The research gaps**

Chemical looping combustion could be used for solid fuel or gaseous fuel. The challenge of fuel types was different. The solid fuel for CLC is coal or biomass. The significant problem of solid fuel is the unburnt char because of the slow gasification step. For the gaseous fuel system, mostly, it is complete combustion. Nonetheless, the improper operation condition was also the reason for incomplete combustion as well. The consequence of incomplete combustion was the CO<sub>2</sub> emission from the air reactor. Accordingly, the operation conditions were also crucial factors for suitable hydrodynamic behavior in the CLC reactors.

### **3.2.2 The objectives**

The dimension of the dual circulating fluidized bed reactor was selected from the study of Su et al. [97]. However, the fuel and oxygen carriers from this study were coal and iron oxide, respectively. Therefore, the system of coal and iron oxide was first investigated to obtain the proper hydrodynamics in the reactor. After that, the system of methane and nickel oxide was investigated in the second part, as shown in Fig. 3.2.1.

For the first section, the operating conditions of the reactors were systematically investigated for suitable hydrodynamic behavior. The fuel and oxygen carriers for this section were coal and iron oxide (Fe<sub>2</sub>O<sub>3</sub>/Fe<sub>3</sub>O<sub>4</sub>).

For the second section, the operating condition which obtained the highest thermal efficiency from chapter 4 was investigated for suitable hydrodynamic behavior, conversion and temperature achievement. The fuel and oxygen carrier for this section was CH<sub>4</sub> and nickel oxide (NiO/Ni).

Fig. 3.2.1 The methodology of hydrodynamic behavior of CLC reactor investigation

### 3.2.3 Model description

The hydrodynamic behavior in a two-dimensional CLC system was investigated. The dual circulating fluidized bed reactor (DCFBR) was selected in this investigation. This reactor consisted of an air reactor and fuel reactor, as shown in Fig. 3.2.2. The reactor configuration was modified from Su et al.'s study. [97] In this study, the downer and air reactor were larger than those compared with Su's study. Accordingly, the solid in the system was more than Su's work. Besides, there was much solid retention in the downer and loop seal. The loop seal was the section that connected the downer and the riser. It was a key point for preventing the reverse flow at the loop seal. The air reactor (AR) was the inner reactor and the fuel reactor (FR) was the outer reactor. Fuel was oxidized by an oxygen carrier at the riser of the fuel reactor. Its products were  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , and spent oxygen carrier.  $\text{CO}_2$  and  $\text{H}_2\text{O}$  were discharged at a cyclone of the fuel reactor. The air was used to regenerate the spent oxygen carrier at the air reactor. There were two types of fuel in the section; coal and natural gas.

Fig. 3.2.2 The dimension of DCFBR. [97]

### 3.2.4 The first section

In this section, coal was used as the fuel and  $\text{Fe}_2\text{O}_3/\text{Fe}_3\text{O}_4$  was used as the oxygen carrier.

#### 3.2.4.1 Methodology for the first part

There were three phases (Eulerian-Eulerian); gases, coal, and a solid sorbent in the model. In this hydrodynamic model, the drag model was Gidaspow; The heat transfer coefficient model was Gunn and the viscous model was k-epsilon. The oxygen carrier was  $\text{Fe}_2\text{O}_3/\text{Fe}_3\text{O}_4$ . In the fuel reactor riser, coal was gasified to char and gas species by  $\text{CO}_2$ .  $\text{Fe}_2\text{O}_3$  oxidized char and gas species. Subsequently,  $\text{Fe}_2\text{O}_3$  was transformed to be  $\text{Fe}_3\text{O}_4$ . In the air reactor or the riser, the spent metal oxide,  $\text{Fe}_3\text{O}_4$ , was regenerated to  $\text{Fe}_2\text{O}_3$  by air. The boundary and initial conditions for this section were shown in Table 3.2.1.

The investigation of the operation condition was systematically designed by using a  $3^k$  factorial experimental design. There were two operation parameters: 1) the system temperature and 2) the ratio between the coal feeding velocity to the weight of the oxygen carrier. The responses of this analysis were % combustible gas species from the FR and %  $\text{CO}_2$  from the AR. The total case studies were nine. The three levels of temperature were 1173, 1373, 1573 K. In the study of Petriz-Prieto, the temperature in the range of 1373-1623 K was investigated. However, the study has not revealed the effect of temperature on the hydrodynamic behavior of the reactor. [49] The total  $\text{Fe}_2\text{O}_3/\text{Fe}_3\text{O}_4$  in the system was 400 kg. The three levels of gas velocity were 0.1, 0.5, and 1.0 m/s. Accordingly, the three levels of the ratio between coal feeding velocity to the weight of the oxygen carrier were 0.00025, 0.00125 and 0.0025 (m/s)/kg, as shown in Table 3.2.2.

**Table 3.2.1** Boundary and initial conditions for the first section.

<b>Boundary conditions</b>	
Right of FR loop seal velocity (m/s)	0
Left of FR loop seal velocity (m/s)	0.00353
Right of AR loop seal velocity (m/s)	0
Left of AR loop seal velocity (m/s)	0.0027
CO <sub>2</sub> velocity inlet at FR riser (m/s)	1.2
CO <sub>2</sub> velocity inlet at coal feeding (m/s)	4
Air velocity inlet at AR riser (m/s)	1.6
Outlet pressure of AR cyclone (pa)	2000
<b>Initial conditions</b>	
Fe <sub>2</sub> O <sub>3</sub> mass fraction at AR downer	1
Fe <sub>2</sub> O <sub>3</sub> volume fraction at AR downer	0.6
Bed height of AR downer (m)	1.28
Fe <sub>3</sub> O <sub>4</sub> mass fraction at FR downer	1
Fe <sub>3</sub> O <sub>4</sub> volume fraction at FR downer	0.6
Bed height of FR downer (m)	1.42

**Table 3.2.2** The total case studies from 3<sup>k</sup> factorial experimental design and the results.

Case	Temperature (K)	V <sub>coal</sub> to weight of OC (m/s)/(kg)
1	1173	0.00025
2	1373	0.00025
3	1573	0.00025
4	1173	0.00125
5	1373	0.00125
6	1573	0.00125
7	1173	0.0025
8	1373	0.0025
9	1573	0.0025

### 3.2.4.2. The equations for CFD simulation included of this followed.

[98]

#### 3.2.4.2.1. Governing equation

a) Conversion of mass

i. Gas phase

$$\frac{\partial}{\partial t}(\varepsilon_g \rho_g) + \nabla \cdot (\varepsilon_g \rho_g v_g) = 0 \quad (3.2.1)$$

ii. Solid phase

$$\frac{\partial}{\partial t}(\varepsilon_s \rho_s) + \nabla \cdot (\varepsilon_s \rho_s v_s) = 0 \quad (3.2.2)$$

b) Conversion of momentum

i. Gas phase

$$\frac{\partial}{\partial t}(\varepsilon_g \rho_g v_g) + \nabla \cdot (\varepsilon_g \rho_g v_g v_g) = -\varepsilon_g \nabla P + \nabla \cdot \tau_g + \varepsilon_g \rho_g g + \beta_{gs}(v_g - v_s) \quad (3.2.3)$$

ii. Solid phase

$$\frac{\partial}{\partial t}(\varepsilon_s \rho_s v_s) + \nabla \cdot (\varepsilon_s \rho_s v_s v_s) = -\varepsilon_s \nabla P + \nabla \cdot \tau_s - \nabla P_s + \varepsilon_s \rho_s g + \beta_{gs}(v_g - v_s) \quad (3.2.4)$$

c) Conversion of solid phase fluctuating energy

$$\frac{3}{2} \left[ \frac{\partial}{\partial t} \varepsilon_s \rho_s \theta + \nabla \cdot (\varepsilon_s \rho_s \theta) v_s \right] = (-\nabla p_s I + \tau_s) : \nabla v_s + \nabla \cdot (\kappa_s \nabla \theta) - \gamma_s + \phi_s \quad (3.2.5)$$

#### 3.2.4.2.2. Constitutive equations

a) Gas phase stress

$$\tau_g = \varepsilon_g \mu_g \left[ \nabla v_g + (\nabla v_g)^T \right] - \frac{2}{3} \varepsilon_g \mu_g (\nabla \cdot v_g) I \quad (3.2.6)$$

b) Solid phase stress

$$\tau_s = \varepsilon_s \mu_s [\nabla v_s + (\nabla v_s)^T] + \varepsilon_s \left( \xi_s - \frac{2}{3} \mu_s \right) \nabla \cdot v_s I \quad (3.2.7)$$

c) Collisional dissipation of solid fluctuating energy

$$\gamma_s = 3(1 - e^2) \varepsilon_s^2 \rho_s g_0 \theta \left( \frac{4}{d} \sqrt{\frac{\theta}{\pi}} \right) \quad (3.2.8)$$

d) Radial distribution function

$$g_0 = \left[ 1 - \left( \frac{\varepsilon_s}{\varepsilon_{s,max}} \right)^{1/3} \right]^{-1} \quad (3.2.9)$$

e) Solid phase pressure

$$p_s = \varepsilon_s \rho_s \theta [1 + 2g_0 \varepsilon_s (1 - e)] \quad (3.2.10)$$

f) Solid phase shear viscosity

$$\mu_s = \frac{4}{5} \varepsilon_s p_s d g_0 (1 + e) \sqrt{\frac{\theta}{\pi}} + \frac{10 \rho_s d \sqrt{\pi \theta}}{96(1+e)g_0 \varepsilon_s} \left[ 1 + \frac{4}{5} g_0 \varepsilon_s (1 + e) \right]^2 \quad (3.2.11)$$

g) Solid phase bulk viscosity

$$\xi_s = \frac{4}{3} \varepsilon_s p_s d g_0 (1 + e) \sqrt{\frac{\theta}{\pi}} \quad (3.2.12)$$

h) Exchange of the fluctuating energy between gas and solid

$$\phi_s = -3\beta_{gs}\theta \quad (3.2.13)$$

i) Gas–solid phase interphase exchange coefficient

Gidaspow model

$$\text{when } \varepsilon_g > 0.80; \beta_{gs} = \frac{3(1-\varepsilon_g)\varepsilon_g}{4d} \rho_g |v_g - v_s| C_{D0} \varepsilon_g^{-2.65} \quad (3.2.14)$$

$$\text{when } \varepsilon_g \leq 0.80; \beta_{gs} = 150 \frac{(1-\varepsilon_g)^2 \mu_g}{\varepsilon_g d^2} + 1.75 \frac{(1-\varepsilon_g) \rho_g |v_g - v_s|}{d} \quad (3.2.15)$$

with

$$Re_k < 1000; C_{D0} = \frac{24}{Re_k} (1 + 0.15 Re_k^{0.687}); Re_k = \frac{\rho_g \varepsilon_g |v_g - v_s| d}{\mu_g}$$

$$Re_k \geq 1000; C_{D0} = 0.44$$

$$\text{when } 0.74 \leq \varepsilon_g \leq 0.82; \omega(\varepsilon) = -0.5760 + \frac{0.0214}{4(\varepsilon_g - 0.7463)^2 + 0.0044}$$

$$\text{when } 0.82 < \varepsilon_g \leq 0.97; \omega(\varepsilon) = -0.0101 + \frac{0.0038}{4(\varepsilon_g - 0.7789)^2 + 0.0040}$$

$$\text{when } \varepsilon_g > 0.97; \omega(\varepsilon) = -31.8295 + 32.8295 \varepsilon_g$$

### 3.2.4.2.3 The reactions for the coal reduction and the iron oxide oxidation

**Coal pyrolysis reaction [97, 99]**

The reaction rate of pyrolysis was followed;

$$r_{pyrolysis} = (1 \times 10^{-3})(0.3(2 \times 10^5) \exp(-104.6/RT) + (1.3 \times 10^7) \exp(-167.4/RT))C_{coal} \quad (3.2.17)$$

**Char gasification reaction [100]**

The reaction rate of char gasification was followed;

$$r_{char} = \frac{(8.83 \times 10^4) \rho_{char} \varepsilon_{char} r_g (1 - x_{char})^{2/3}}{MW_{char}} \quad (3.2.19)$$

$r_{char}$  (kmol/m<sup>3</sup>/s) was char gasification rate,  $\rho_{char}$  (kg/m<sup>3</sup>) was char density,  $\varepsilon_{char}$  was char volume fraction,  $x_{char}$  was char conversion, and  $MW_{char}$  was char molecular weight.

**Methane reduction reaction [101, 102]**

The reaction rate of methane reduction was followed;

$$r_{CH_4} = \frac{(0.30085) k_{CH_4}(x) \rho_{Fe_2O_3} (m_{ox}) Y_{CH_4}}{0.2(MW_{O_2})} \quad (3.2.21)$$

Where;

$$x = \frac{m_{ox}}{m_{ox} - m_{red2}}$$

$$m_{ox} = Y_{Fe_2O_3} + Y_{Fe_3O_4} \frac{12MW_{Fe_2O_3}}{8MW_{Fe_3O_4}} \quad (3.2.22)$$

$$m_{red2} = Y_{Fe_2O_3} \frac{8MW_{Fe_3O_4}}{12MW_{Fe_2O_3}} + Y_{Fe_2O_3} \quad (3.2.23)$$

$$k_{CH_4} = 3.37598 \exp(-49/RT) C_{CH_4}^{1.3} \quad (3.2.24)$$

**Ethane reduction reaction** [101, 102]

The reaction rate of ethane and methane reduction were equal.

$$r_{\text{C}_2\text{H}_6} = r_{\text{CH}_4} \quad (\text{R 4.4}) \quad (3.2.26)$$

**Carbon monoxide reduction**

The reaction rate of carbon monoxide reduction was followed;

$$r_{\text{H}_2} = \frac{(2)(0.30085)k_{\text{CO}}(\rho_{\text{Fe}_2\text{O}_3})(m_{\text{ox}})(1-x)^{2/3}}{MW_{\text{O}_2}} \quad (3.2.28)$$

Where;

$$k_{\text{CO}} = 0.65410 \exp(-20/RT) C_{\text{CO}} \quad (3.2.29)$$

**Hydrogen reduction** [101, 102]

The reaction rate of hydrogen reduction was followed;

$$r_{\text{H}_2} = \frac{(2)(0.30085)k_{\text{H}_2}(\rho_{\text{Fe}_2\text{O}_3})(m_{\text{ox}})(1-x)^{2/3}}{MW_{\text{O}_2}} \quad (3.2.31)$$

Where;

$$k_{\text{H}_2} = 2.42648 \exp(-24/RT) C_{\text{H}_2}^{0.8} \quad (3.2.32)$$

**Water gas shift reaction** [103]

The reaction rate of water gas shift was followed;

$$r_{\text{CO}} = -2.17 \times 10^7 \exp(-192/RT) \left( C_{\text{H}_2}^{0.5} C_{\text{CO}_2} - \frac{C_{\text{H}_2\text{O}} C_{\text{CO}}}{\exp(-4.33 + (4577.8/T))} \right) \quad (3.2.34)$$

**Iron oxide oxidation** [101, 102]

The reaction rate of carbon monoxide reduction was followed;

$$r_{\text{H}_2} = \frac{(2)(0.30085)k_{\text{O}_2}(\rho_{\text{Fe}_2\text{O}_3})(m_{\text{ox}})(1-x)^{2/3}}{MW_{\text{O}_2}} \quad (3.2.36)$$

Where;

$$k_{\text{O}_2} = 0.63669 \exp(-20/RT) C_{\text{O}_2} \quad (3.2.37)$$

### 3.2.5 The second section

In this section, methane ( $\text{CH}_4$ ) was used as the fuel and NiO/Ni was used as the oxygen carrier.

#### 3.2.5.1 Methodology for the second section

In this model, the drag model was Gidaspow, the heat transfer coefficient model was Gunn, and the viscous model was k-epsilon, as the same in the first part. The difference from the first part would be mentioned as followed. There were two phases (Eulerian-Eulerian); gases and solid sorbent. The oxygen carrier was NiO/Ni. In the fuel reactor riser,  $\text{CH}_4$  was mixed with  $\text{CO}_2$ . The mixture was introduced into the riser of the fuel reactor. NiO oxidized the  $\text{CH}_4$ . The gas products were  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . The solid product was Ni. In the air reactor riser, the spent metal oxide, Ni, was regenerated to NiO by air. The boundary and initial conditions for this section were shown in Table 3.2.3. At the initials, the solid was patched in the reactor downer. The gas mixture was patched in the reactor riser to reduce the temperature deviation from the gas density changing.

**Table 3.2.3** Boundary and initial conditions for the second section.

<b>Boundary conditions</b>	
Right of FR loop seal velocity (m/s)	0
Left of FR loop seal velocity (m/s)	0.00353
Right of AR loop seal velocity (m/s)	0
Left of AR loop seal velocity (m/s)	0.0027
CO <sub>2</sub> velocity inlet at FR riser (m/s)	1.2
Air velocity inlet at AR riser (m/s)	1.6
Outlet pressure of AR cyclone (pa)	2000
<b>Initial conditions</b>	
Reactor temperature and the inlet stream (K)	873
Ni mass fraction at AR downer	0.277
Al <sub>2</sub> O <sub>3</sub> mass fraction at AR downer	0.723
Solid volume fraction at AR downer	0.35/0.45
Bed height of AR downer (m)	1.28
NiO mass fraction at FR downer	0.277
Al <sub>2</sub> O <sub>3</sub> mass fraction at FR downer	0.723
Solid volume fraction at FR downer	0.35/0.45
Bed height of AR downer (m)	1.42
CH <sub>4</sub> mass fraction at FR riser	0.3
CO <sub>2</sub> mass fraction at FR riser	0.7
Bed height of FR riser (m)	1.50
O <sub>2</sub> mass fraction at AR riser	0.168
N <sub>2</sub> mass fraction at AR riser	0.2
H <sub>2</sub> O mass fraction at AR riser	0.632
Bed height of AR riser (m)	1.35

The crucial point for the model in this system was the properties of the mixture, such as density, the heat of formation, heat capacity. The properties must be checked in the mixture section of the Ansys fluent programs. The properties of the mixture were acquired from Perry's chemical engineers' handbook. [104] The accurate properties data led to the accuracy of the results.

The aim of this section was the using operation conditions from the chapter 4. The rate reaction, initial solid volume fraction, velocity and CH<sub>4</sub> mass fraction in feed were investigated to obtain the suitable hydrodynamic behavior. The pre-exponential

factor of reaction rate was adjusted at 1, 1E+3 and 1E+5. The initial solid volume fraction was adjusted at 0.35 and 0.45. The velocity was adjusted from the previous section at 1 and 1.5 times. The CH<sub>4</sub> mass fraction in feed was adjusted at, 0.05, 0.15 and 0.30, as shown in Table 3.2.4. The total cases were 10 cases. After that, the simulation data was validated with the temperature, CH<sub>4</sub> conversion and MW thermal of the experimental data.

**Table 3.2.4** The adjusted parameters

Cases	Rate constant	Volume fraction of solid phase	Velocity when compare with base case	Mass fraction of CH <sub>4</sub> at feed
1	1	0.35	1	0.3
2	1	0.45	1	0.3
3	1.00E+03	0.35	1	0.3
4	1.00E+03	0.45	1	0.3
5	1.00E+05	0.35	1	0.3
6	1.00E+05	0.45	1	0.3
8	1.00E+05	0.45	1	0.15
7	1.00E+05	0.45	1	0.05
9	1.00E+05	0.35	1.5	0.3
10	1.00E+05	0.45	1.5	0.3

### **3.3 Methodology for chapter 6; the sustainability assessment of chemical looping combustion for power production**

#### **3.3.1. The research gaps**

In a previous CLC study, the best case of the CLC process was investigated only thermal efficiency and economic analysis. However, the study did not investigate whether those implementations would enhance the sustainability of the improved CLC processes. The significance of thermal efficiency to the sustainability of the CLC process had not been reported. The approach for CLC process improvement by sustainability analysis was reported, as well. There were 6 case studies in which different operation conditions and configurations were investigated. The best case of 3 viewpoints (thermal efficiency, economic analysis, and sustainability analysis) was proposed. The comparison among the 3-analysis types has not been performed before. Besides, this study revealed the results, comparing combustion types between conventional combustion (CC) and CLC, the effect of the CO<sub>2</sub> capture efficiency of the CC, and the effect of thermal efficiency on sustainability analysis. The interesting point was the approach of the operation condition or configuration of the case study that obtained high sustainability was suggested in this study.

#### **3.3.2. Objective**

Perform energy analysis for sustainability assessment

#### **3.3.3. Methodology**

The main objectives of this section were the sustainability assessment of the CLC process. In addition, there was an investigation of the impact of combustion types and the impact of system configuration to the 3 points of view, thermal efficiency analysis, economic analysis and sustainability analysis. The CLC process was the combustion unit that almost captures CO<sub>2</sub> in flue gas with a simple process. The other process that had to compare with the CLC process was the combustion process that included the CO<sub>2</sub> capture also. This comparison would express the impact of combustion types on sustainability. Accordingly, the conventional combustion (CC) with solid adsorption and the CLC process were selected to compare. The CLC

process for power production was achieved high thermal efficiency. The high thermal efficiency indicated the efficiency of fuel usage in power production. There was not an investigation of the significance of thermal efficiency to sustainability. Accordingly, the significance of efficiency improvement of the CLC process was the one topic in the sustainability assessment of the CLC process. The benefit of this section would be the first time that represents the sustainability assessment of the CLC process. It could be a new proposal for the CLC process improvement in the future, as shown in Fig. 3.3.1

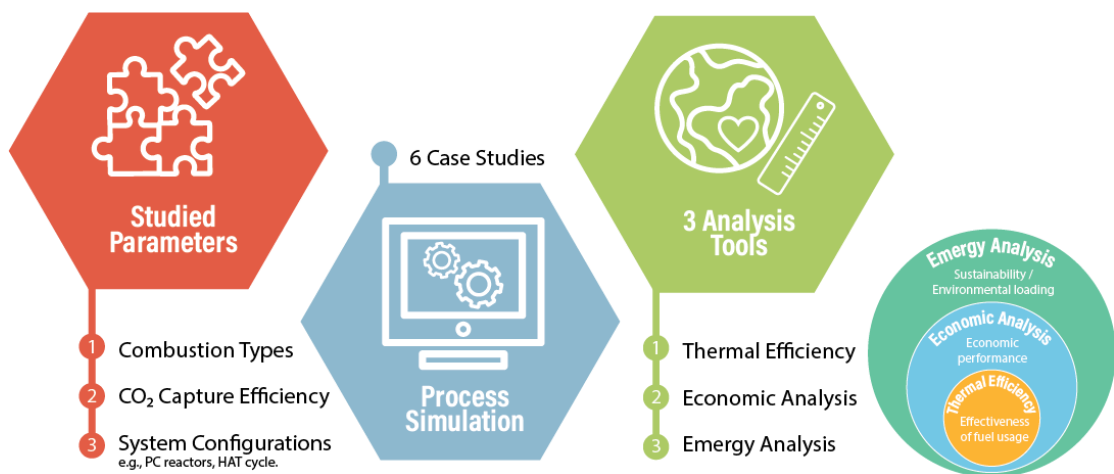

Fig. 3.3.1 The graphical abstract of the sustainability of CLC process investigation

The comparison of combustion types for decision-making in a sustainability viewpoint between the CC with solid adsorption and the CLC process was developed and investigated. The total cases for this investigation were 6 cases. Cases 1-3 were CC cases and cases 4-6 were CLC cases. The brief operation of all case study was shown in Fig. 3.3.2.

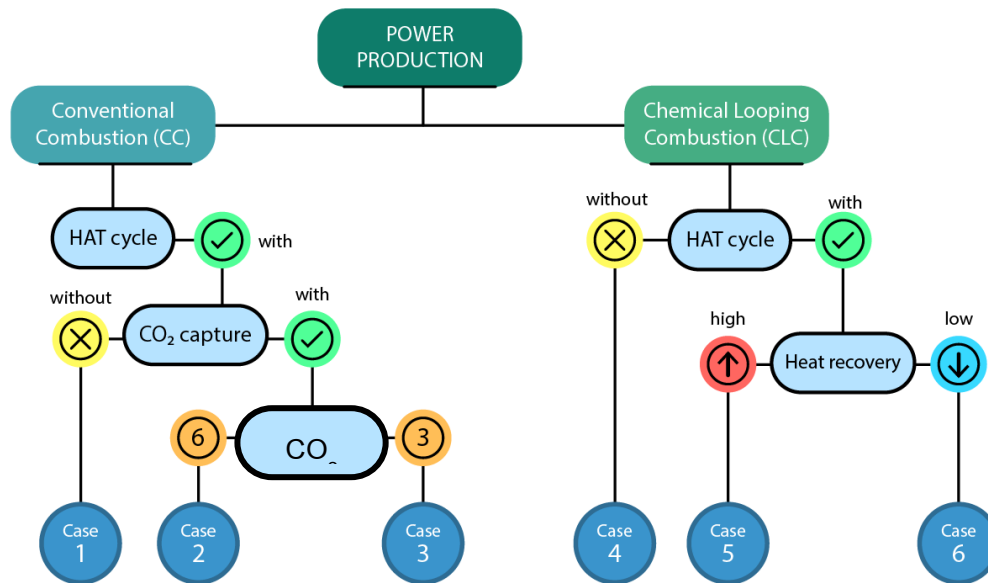

Fig. 3.3.2 The system configurations of all case studies

The significant section for power production was the HAT cycle. HAT cycle was the power production unit that obtained high thermal efficiency. It consisted of a multi-stage compressor which it had an intercooler between the compressor stage. This cycle increased the thermal efficiency of the power plant by decrease the work consumption of the compression process. The decrease in compressed air temperature was the reason for the work consumption of compression reduction. The operation of compression in this case study was method 3 because of its increased temperature of the combustion reactor and power production. The compression operation of case 6 was method 2 because the work consumption of compression from method 2 was the lowest. In other multi-stage compressor studies, its compression ratio of every stage was equal, which was corresponding to method 2 in case 6. [93] The compression ratio affected power production and thermal efficiency, as well. In the compression operation of all case studies except case 6, the compression ratio was 1.115, 1.38 and 9.75, for stages 1, 2 and 3, respectively. In the last stage compressor, it was 65% of total pressure change. Accordingly, this operation increased the temperature of the compressed air before it was introduced to the combustion section. In this compression operation, the work consumption of compression was the highest workload. However, the power production and thermal efficiency of this operation

were the highest obtaining. The compression operation of case 6 was different from others. The compression ratio of all stages was 2.466.

In the CC case, there were three major sections; 1) combustion section, 2) HAT cycle for power production (Fig.3.3.1), and 3) solid adsorption for CO<sub>2</sub> capture. Case 1 was the CC case that was not employed solid adsorption. There were only a combustion section and the HAT cycle. The analysis from cases would be to express the impact of the process without CO<sub>2</sub> capture. Cases 2 and 3 were the CC case that employed three major sections, which stated above. The difference between cases 2 and 3 was the CO<sub>2</sub> capture efficiency in the CO<sub>2</sub> capture section, 96.22% and 77.66% in case 2 and case 3, respectively. Accordingly, the effect of the CO<sub>2</sub> capture efficiency would be investigated from 3 points of view. In the CO<sub>2</sub> capture section, the operation conditions were followed Boonprasop study. [105-107] The multi-stage CO<sub>2</sub> capture reactor was the main section of the CO<sub>2</sub> capture section. The solid sorbent in CC cases was Na<sub>2</sub>CO<sub>3</sub>. [16]

In CLC cases, there were 3 major sections; 1) CLC process for combustion and CO<sub>2</sub> separation and 2) HAT cycle. Case 3 was the CLC case that was not employed the HAT cycle. Case 3 was the only CLC process without a multi-stage compressor from the HAT cycle. HAT cycle was the power production that reduced the work consumption of compression. Since the HAT cycle was not employed in case 4, therefore the thermal efficiency of case 4 would be the lowest of all case studies. Moreover, the equipment cost of case 4 would be the lowest of all, as well. The effect of low thermal efficiency and low equipment cost on the 3 points of view would be analyzed. Cases 5 and 6 were the CLC case that employed 2 major sections, which stated above. The operation conditions of case 4 led to the highest thermal efficiency obtaining. The heat recovery and the type of compression operation of case 4 were the cause of high equipment cost. The operation condition of case 6 was adjusted; low heat recovery and type of compression operation. Accordingly, the thermal efficiency of case 6 was slightly lower than case 5.

For all six case studies, the power plants were operated at a 50 MW capacity using natural gas as the feedstock. The case studies were developed with the ASPEN PLUS process simulation software using Peng-Robinson-Boston-Mathias for thermodynamics properties [49]. This simulation was considered as the adiabatic

process for obtain the highest efficiency of the system. The solid metal inventory in the process was 700 kg/MW<sub>th</sub> for all case studies [108]. The RGibbs reactor was used for air and fuel reactor. The RYield was used for CO<sub>2</sub> capture reactor. RYield is suitable to determine the conversion of each stage to consistent with experimental data. [105-107] The minimum temperature approach of heat exchanger was 10°C. The isentropic efficiency of compressor and turbine was 90% . The parameters related to the case studies are presented in Table 1 for cases 1-3, and in Table 2 for cases 4–6. The parameters in CC cases and CLC cases were shown in Table 3.3.1 and Table 3.3.2, respectively. The process description of case studies would be explained in the following section.

**Table 3.3.1** Conditions of cases 1-3.

### 3.3.3.1. Process descriptions

#### HAT Cycle

In HAT cycle, air was compressed by the multi-stage compressor and was reduced temperature by the intercooler which was between compressors. Therefore, the fresh air was introduced into C-101, HX-101, C-102, HX-102, and C-103, respectively, as shown in Fig. 3.3.3. Water gained the heat from the compressed air and HX-101 and HX-102, respectively. Water and compressed air were preheated and generated to be the humid air, before introduced to air reactor.

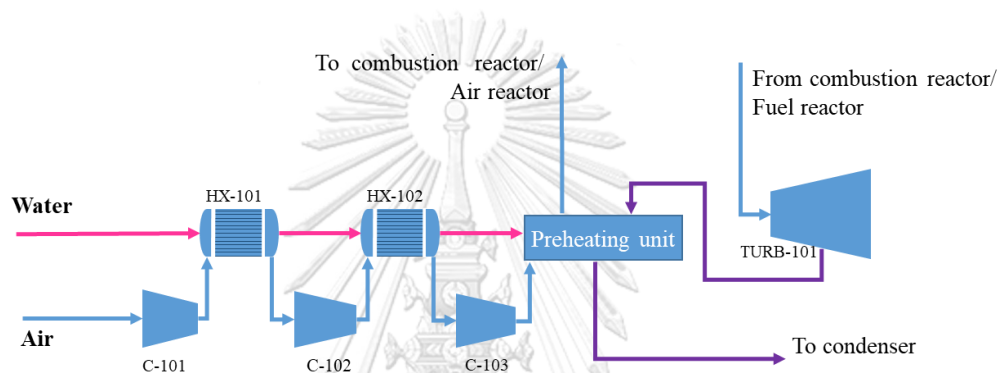

Fig. 3.3.3 Flowchart of a HAT cycle

#### Case 1: CC and HAT cycle without CO<sub>2</sub> capture

Case 1 was the CC and HAT cycle. The CO<sub>2</sub> capture process was not employed in this case. The flow diagram of case 1 was shown in Fig. 3.3.4. The 3 major sections of this case were the natural gas preheating section, combustion chamber (CB-101), and HAT cycle section. After that, the compressed air and water were introduced to the preheating section. The discharged from turbine (TRUB-101) was the heat source which was used to preheat natural gas, water, and air. Natural gas was preheated before it was introduced into CB-101 for combustion. The flow chart of natural gas preheating was shown in Fig. 3.3.5. Natural gas was preheated by high temperature turbine discharge at HXF-101 and HXF-102, and water was preheated at HX-201. Compressed air was preheated at HX-202. Water and compressed air were preheated by the discharged turbine, as well. The analysis of this case will reveal the power plant performance that was not employed CO<sub>2</sub> capture section in 3 points of view.

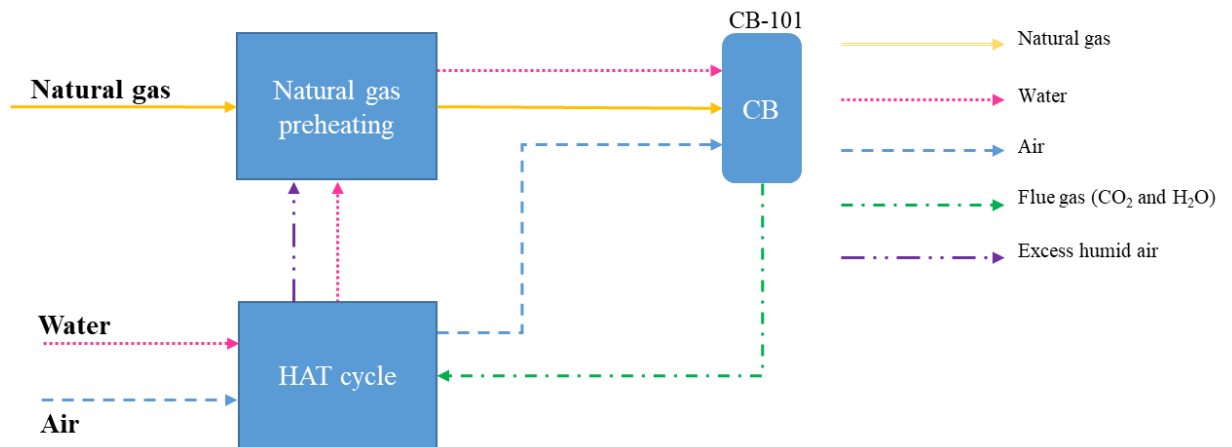

Fig. 3.3.4 Flow process of CB with a HAT cycle and CO<sub>2</sub> capture process (case 1)

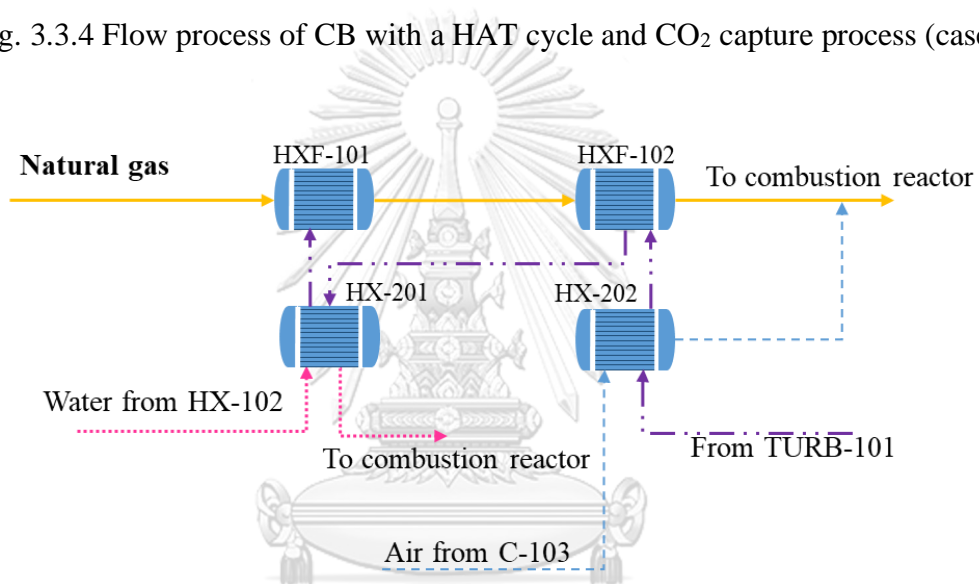

Fig. 3.3.5 Flow chart of natural gas preheating for case 1

**Case 2: CC and HAT cycle with 96.22% CO<sub>2</sub> capture and Case 3: CC and HAT cycle with 77.76% CO<sub>2</sub> capture.**

Case 2 and case 3 were the CC with the CO<sub>2</sub> capture section. The flow chart of cases 2 and 3 were shown in Fig. 3.3.6. There were 5 sections in these cases; natural gas preheating, combustion (CC), HAT cycle, CO<sub>2</sub> capture process, and condenser (CDS). Water and air were introduced into the HAT cycle. Water was used as coolant media in the intercooler. Air was compressed at the multi-stage compressor. They were combined with being humid air and were introduced into the combustion chamber (CC-101). The flue gas from CC-101 was used to preheat other sections. The preheating section was shown in Fig. 3.3.7. Natural gas was preheated at HXF-101

and HXF-102. Water was preheated at HX-201. Compressed air was preheated at HXA-103. Natural gas, water and air were preheated by the discharged turbine (TURB-101). The CO<sub>2</sub> capture efficiency process in case 2 was higher than case 3 because of the higher CO<sub>2</sub> capture reactors. There were six reactors of CO<sub>2</sub> capture in case 2, but 3 reactors for case 3. The CO<sub>2</sub> conversion of each reactor was to follow Boonprasop's study. [105-107] The CO<sub>2</sub> capture and solid regeneration of case 2 and case 3 were shown in Fig. 3.3.8. (a) and Fig. 3.3.8. (b), respectively. The discharged from the turbine after the preheating section was introduced into CO<sub>2</sub> capture reactors. The flue gas, after treated by Na<sub>2</sub>CO<sub>3</sub>, was sent to CYC-101 for separated the spent solid sorbent and treated flue gas. The solid sorbent was preheated by turbine discharge before being regenerated. The regeneration condition was followed by Boonprasop's study, which was shown in Table 3.3.1. The CO<sub>2</sub> and water would be separated from sorbent and they were sent to a condenser (CDS-101) for obtained higher purity of CO<sub>2</sub>. The regenerated sorbent was further used to captured CO<sub>2</sub>. In between CO<sub>2</sub> capture reactors, there was a heat exchanger for temperature reduction. This approach increased CO<sub>2</sub> capture efficiency, as well. Case 2 had 6 reactors; CP-101, CP-102, CP-103, CP-104, CP-105 and CP-106 and 3 heat exchangers; HXC-101, HXC-102, HXC-103. Case 3 had 3 reactors; CP-101, CP-102 and CP-103, and 1 heat exchangers; HXC-101.

Fig. 3.3.6 Flow process of conventional combustion with a HAT cycle and CO<sub>2</sub> capture process (cases 2 and 3)

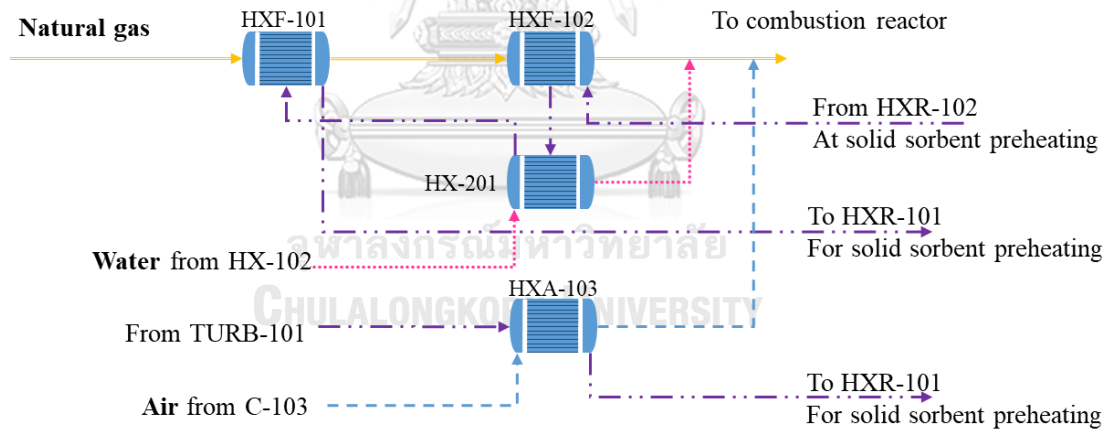

Fig. 3.3.7 Flow chart of natural gas preheating for cases 2 and 3

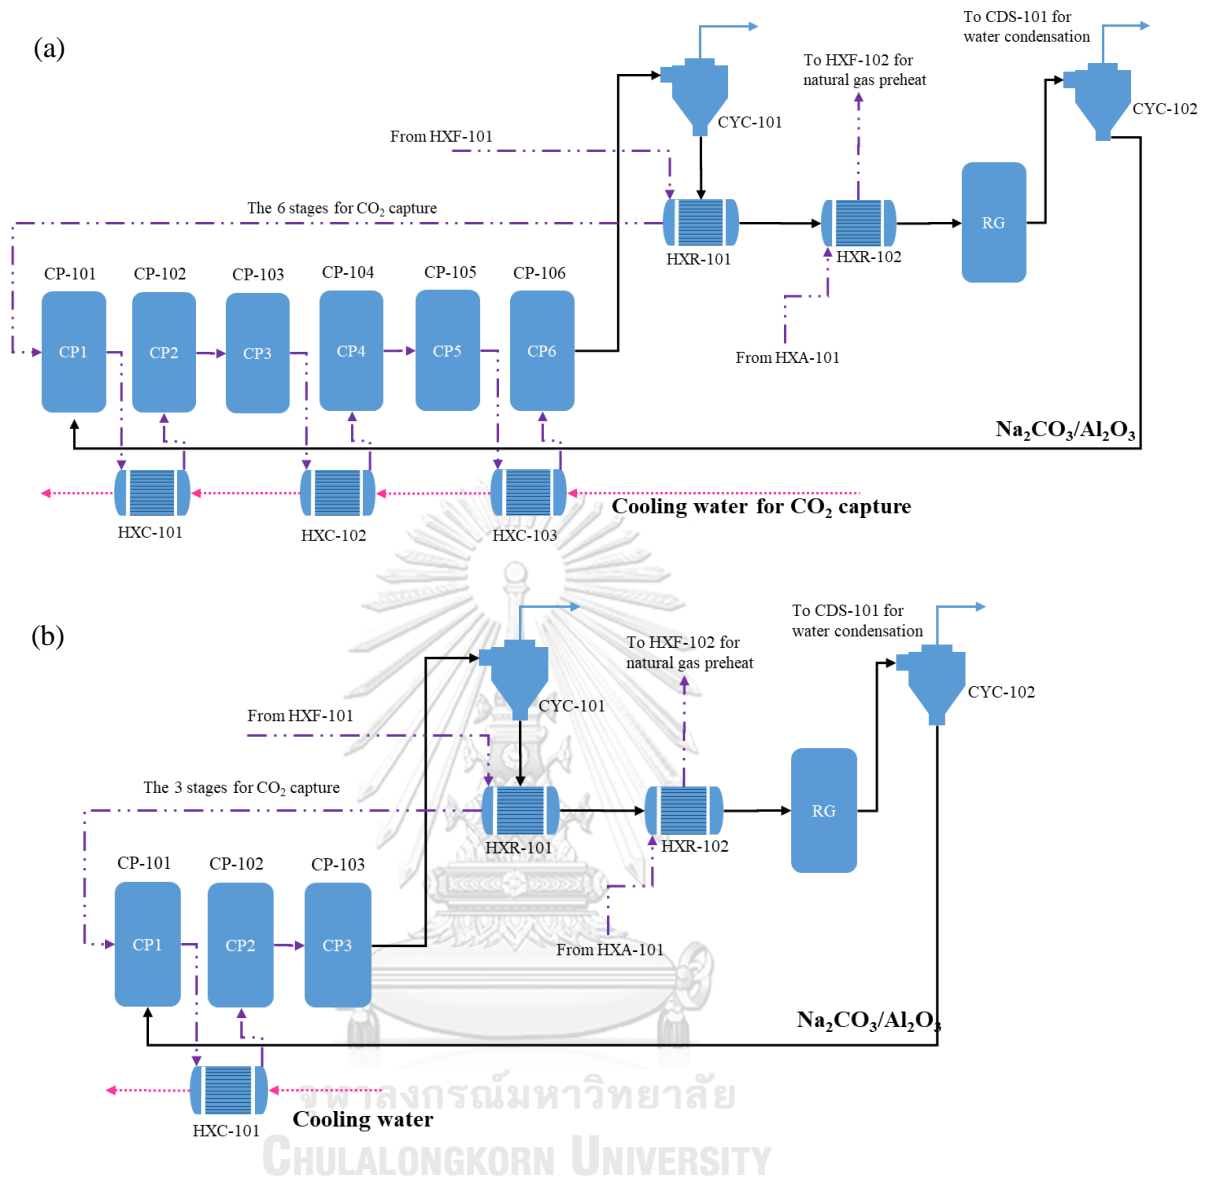

Fig. 3.3.8 Flow chart of CO<sub>2</sub> capture and regeneration process for (a) case 2 and (b) case 3

#### Case 4: CLC without HAT

Case 4 was the only CLC process without a HAT cycle, as shown in Fig. 3.3.9. There were 4 main sections for this case; natural gas and compressed air preheating, CLC, turbine (TURB-101), and condenser (CDS-101). Natural gas was preheated by the turbine discharge. Then it was introduced into CLC. Air was compressed and it was introduced into CLC. After combustion, the flue gas and the excess air were used to preheat in the preheating section. After that, CO<sub>2</sub> was separated from water by CDS. The flow chart of the CLC process was shown in Fig. 3.3.10.

The compressed air from HXA-103 was used to oxidized Ni in the air reactor (AR-101), as shown in 3.3.1. The outlet from the air reactor was sent to a cyclone (CYC-101). The excess air was sent to the turbine (TURB-102) for power production. Natural gas was introduced into the fuel reactor (FR-101). Natural gas was oxidized by NiO, as shown in 3.3.2. Then the outlet from FR-101 was sent to a cyclone (CYC-102). The flue gas was used for power production at the turbine (TURB-101). The discharges from 2 turbines were used in the preheating section.

The flowchart of the preheating section was shown in Fig. 3.3.11. Natural gas was preheated at HXF-101, HXF-102, HXF-103, HXF-104, and HXF-105. Air was compressed at C-101; after that, the compressed air was preheated at HXA-101, HXA-102, and HXA-103. The discharge from TURB-101 was used to preheat at HXF-105, HXA-103, HXF-104, HXF-103, and HXA-101, respectively. Then it would be introduced to CDS-101. The discharge from TURB-102 was used to preheat at HXA-102, HXF-102, and HXF-101, respectively. This case was not employed in the HAT cycle in the process. The thermal efficiency of this case would low, but the equipment cost of this case was low. The economic and sustainability analysis of the low thermal efficiency case would be illustrated in the economic and sustainability analysis part.

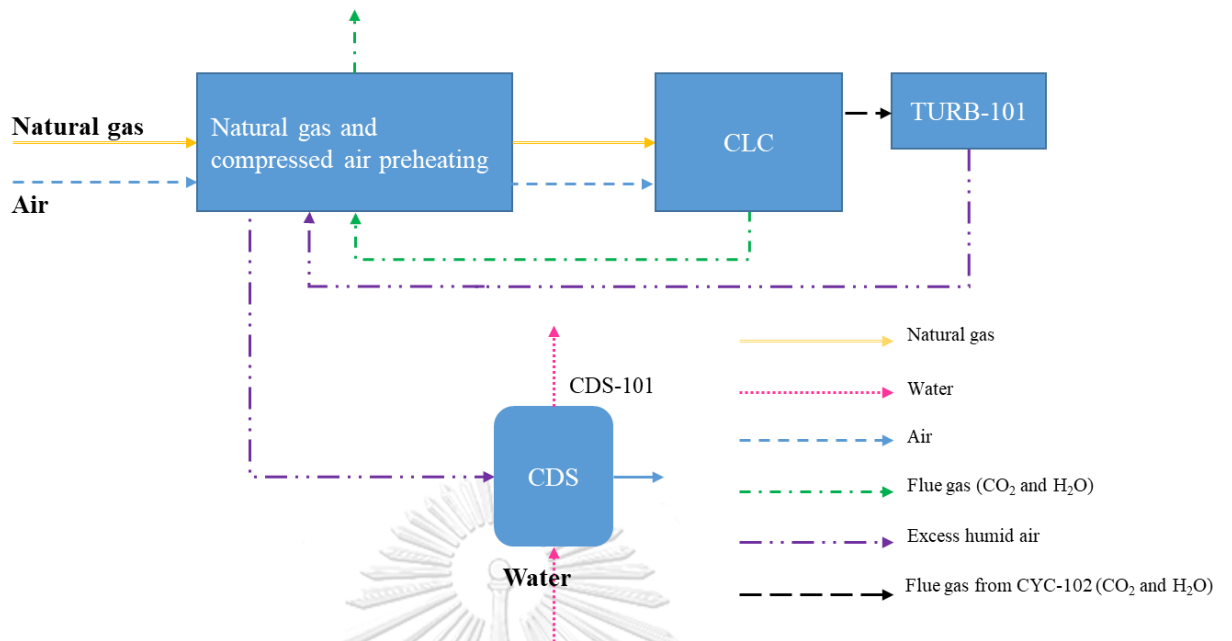

Fig. 3.3.9 Flow process of CLC without a HAT cycle for case 4

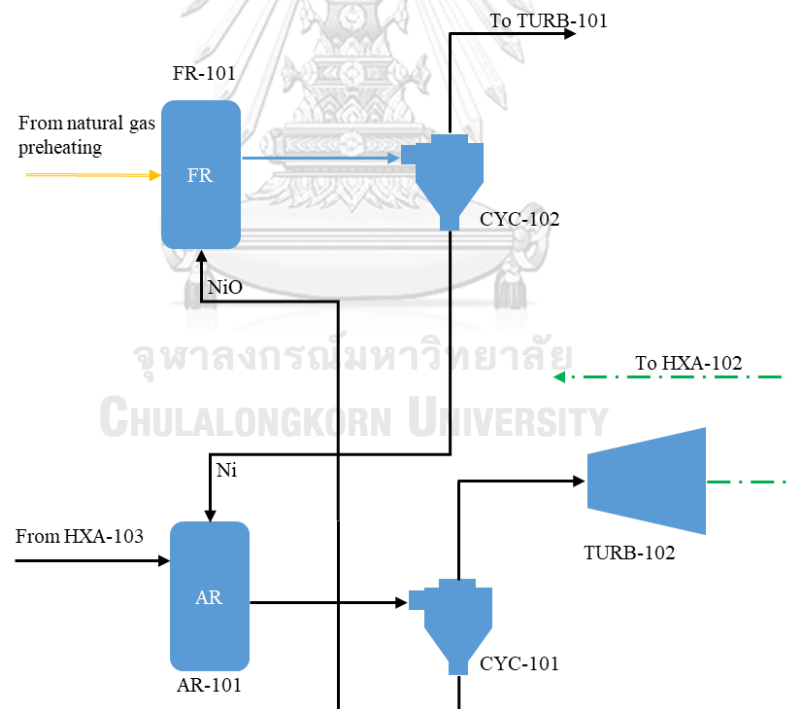

Fig. 3.3.10 Flow chart of the CLC process (a) without a HAT cycle for case 4 and (b) for cases 4, 5, and 6

Fig. 3.3.11 Flow chart of natural gas and compressed air preheating for case 4

### Case 5: CLC with HAT cycle and high heat recovery

Case 5 was the CLC process with the HAT cycle, which was high heat recovery. The flow chart of case 5 was shown in Fig. 3.3.12. There were four major sections; preheating, CLC, HAT cycle, and CDS. Natural gas was preheated, then it was introduced to CLC for heat production and CO<sub>2</sub> separation. Water and air were introduced into the HAT cycle. Then they were preheated and were introduced into CLC, as well. The CO<sub>2</sub> in the flue gas was separated at CDS. CLC process was the heat production unit that inherent separated CO<sub>2</sub>. Accordingly, the thermal efficiency of CLC would higher than CC with the CO<sub>2</sub> capture section. Besides, the operation conditions of this case led to obtaining high thermal efficiency. The compression operation of this case increased power production. This case was high heat recovery. Accordingly, the heat exchanger unit in the preheating section of this case was higher than the others. The flow chart of the preheating section was shown in Fig. 3.3.13. Natural gas was preheated at HXF-101, HXF-102, HXF-103, and HXF-104. Then natural gas was introduced to the fuel reactor (FR-101). The compressed air was preheated at HXA-101. Water was preheated at HXA-102, HXA-103, HXA-104,

HXA-105, and HXA-106 After that, water was dissolved in dry air which it became humid air at mixer. The humid air was preheated at HXA-107, and HXA-108. Humid air was introduced to air reactor (AR-101). The discharged from TURB-101 was used to preheated at HXF-105, HXA-108, HXF-104 HXF-103, and HXA-101. The discharged from TUR-102 was used to preheated at HXA-107, HXA-106, HXF-102, HXA-105, HXA-104, HXA-103, HXA-102, and HXF-101. This case was designed to obtain the highest thermal efficiency. The economic and sustainability analysis of this cases was explained in other section.

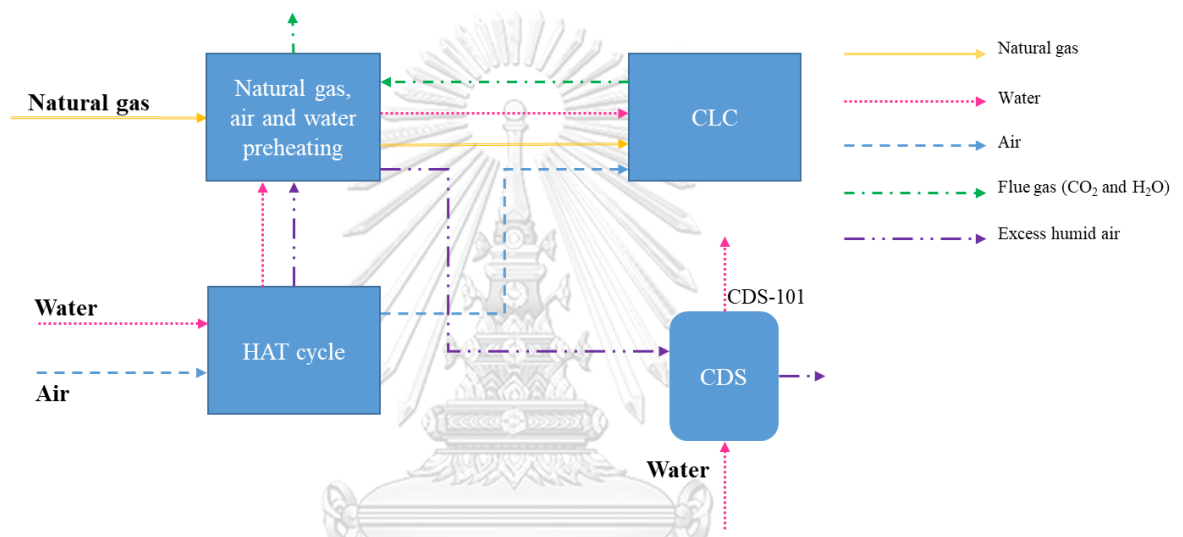

Fig. 3.3.12 Flow chart of CLC with HAT for cases 5 and 6

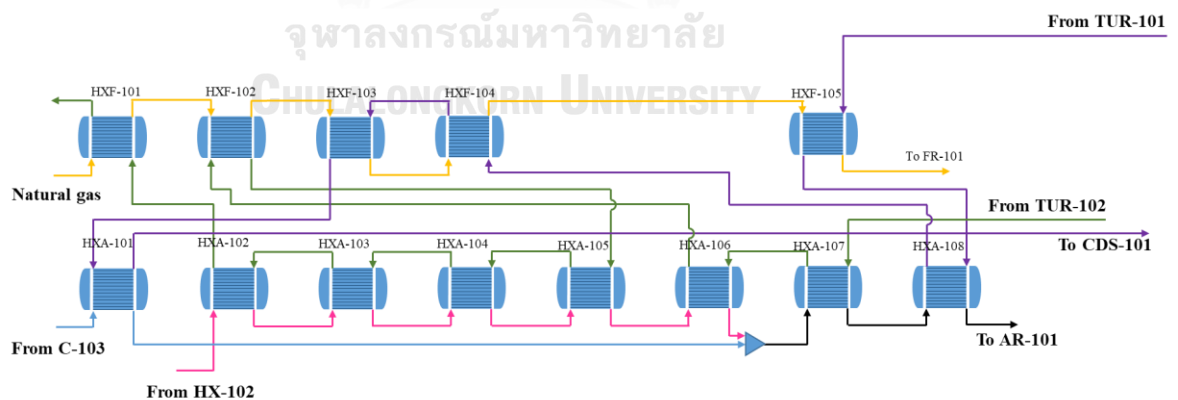

Fig. 3.3.13 Flow chart of natural gas, air and water preheating for case 5

### Case 6: CLC with HAT cycle and low heat recovery

Case 6 was the CLC process with the HAT cycle, which was low heat recovery. The flow chart of this was shown in Fig. 3.3.12. There were four major sections, like case 5, preheating, CLC, HAT cycle, and CDS. The differences between this case and case 5 were the compression operation and the configuration in the preheating unit. The pressure ratio of all stages of this case was equal. The compressor ratio of this case was lower than others, which led to the smaller size of compressors. The preheating section of this case was shown in Fig. 3.3.14. Natural gas was preheated at HXF-101, HXF-102- HXF-103, and HXF-104. The compressed air was preheated at HXA-101. Water was preheated at HXA-102 and HXA-103. After that, the humid air was preheated at HXA-104 and HXA-105. The discharged from turbines were used to preheated in the preheating section. The discharged from TUR-101 were used to preheated at HXF-104, HXA-105, HXF-103 and HXA-101, respectively. The discharged from TUR-102 was used to preheated at HXA-104, HXF-102, HXA-102, and HXF-101.

The heat exchanger units of case 6 were lower than case 5. Therefore, the equipment and total capital cost of case 6 were lower than case 5. The other difference between case 5 and case 6 was the Ni loading in the system. The loadings were 16% and 28%, respectively. The ratio between natural gas and Ni was equal. This increase in Ni loading affected the mass flow rate of  $\text{Al}_2\text{O}_3$  only. When high Ni loading, the mass flow rate of  $\text{Al}_2\text{O}_3$  was low; on the other hand, the  $\text{Al}_2\text{O}_3$  in case 6 was lower than case 5 and the total solid mass flow rate of case 6 was lower than case 5, as well. Solid in the process was utilized in oxygen carrier duty and heat source duty. When the low solid mass flow rate co, the temperature of the fuel reactor was too low, which it deserved the external heat when the low solid mass flow rate. The external heat was the reason for the low thermal efficiency. However, the suitable solid mass flow rate led to adequate heat for the fuel reactor. The lower solid mass flow rate of case 6 led to the high temperature of the air reactor and fuel reactor. This operation would affect thermal efficiency, economy and sustainability, as well.

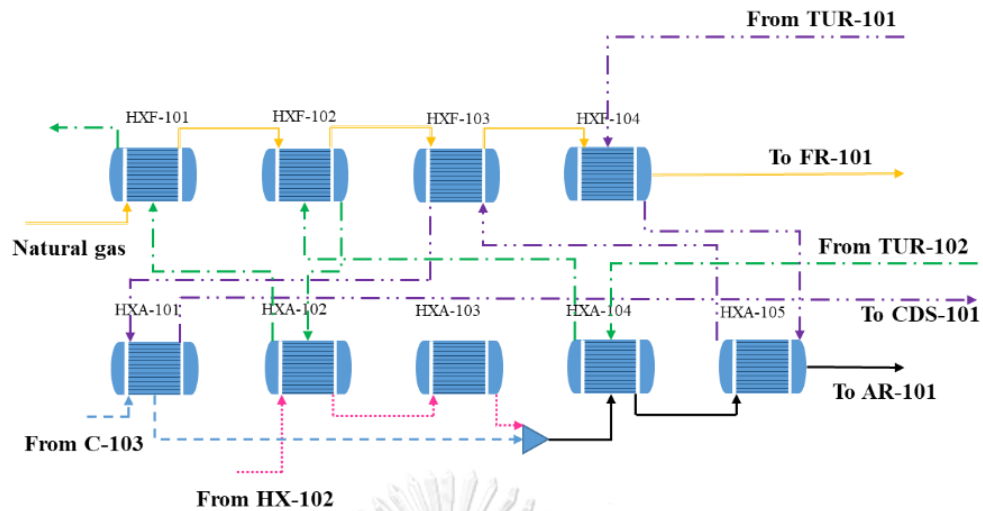

Fig. 3.3.14 Flow chart of natural gas, air and water preheating for case 6

### 3.3.4. Analysis tools

#### 3.3.4.1. Thermal efficiency analysis

Thermal efficiency is calculated from the ratio of net power production divided by the lower heating value of fuel. The net power production was the total power production which subtracted by the power consumption of compression. High efficiency leads to the fuel utilization with efficiency.

$$\text{Thermal efficiency (\%)} = \frac{P_{AR} + P_{FR} - P_C - P_P}{LHV_{NG}} \times 100 \quad (3.3.1)$$

Note that;

$P_{AR}$  = power production from air reactor (kW)

$P_{FR}$  = power production from fuel reactor (kW)

$P_C$  = power consumption from air compressors (kW)

$P_P$  = power consumption from pump (kW)

LHV = lower heating value (kW)

NG = natural gas

#### 3.3.4.2. Economic analysis

The economic analysis indicated the profit of the case study and the competition in economic. The comparison types of CLC work in the previous study were only thermal efficiency and economic analysis. Therefore, it was convenient for

comparing the result of other CLC work with this analysis. The economic result was a preliminary result for deciding on investment by considering the IRR and payback period. Many studies investigated the economic analysis of the CLC process. The chemical looping with the air separation process for oxy-fuel combustion was conducted in the economic analysis by Shi et al. [110]. It was 500 MW power production capacity. However, the 50 MW (thermal) power production was investigated by Olaleye and Wang. [69]

In this study, the total capital investment and operating costs were estimated based on these following assumptions.

- 1) The power plant capacity was 50 MW.
- 2) Lifetime of the plant was 30 years.
- 3) Tax rate was 20%.
- 4) Plant salvage value was estimated from 20% of fixed capital investment (FCI).
- 5) The plant was operated at full capacity (8760 hrs./year).
- 6) The chemical engineering plant index (CEPCI) was 558.5 (January, 2017). [111]

Aspen Plus software and manufacturing cost would be estimated the equipment cost. The other unit operation that was not estimated by Aspen plus software was estimated as followed Turton et al. [96]. Fixed capital investment (FCI) composes of direct cost and indirect cost. The summation of FCI and working capital (WC) is total capital investment (TCI) as shown in Eq. 5.2. Working capital (WC) was 15% of FCI.

$$TCI = FCI + WC \quad (3.3.2)$$

The payback period is the time (years) that the investment reaches the breakeven point. The point that total income equal to total cost is the breakeven point.

The other indicator in economic analysis for comparison is the internal rate of return (IRR). The IRR is the rate that is calculated when the net present value (NPV) was zero value, as shown in Eq. 5.3. It is the return of investment, which was calculated from the beginning to the last year of the plant operation. The high profit of the project led to high IRR, which is more competitive for investment, as well.

$$\sum_{n=0}^M \frac{CF_n}{(1+IRR)^n} = NPV = 0 \quad (3.3.3)$$

Note that

CF = cash flow

n = each period

M = the end of plant operation

IRR = internal rate of return

NPV = net present value

### 3.3.4.3. Carbon tax calculation [112]

The cost of CO<sub>2</sub> emission was included with the cost of the expenses. This cost would be counted in analysis for environmental impact. The carbon tax must be paid when CO<sub>2</sub> was released to the environment, as shown in Eq. 5.4.

The cost of CO<sub>2</sub> emission (\$) = mass flow rate of CO<sub>2</sub> (metric ton/y) x 49 (\$/metric ton) [112] (3.3.4)

### 3.3.4.4. Sustainability evaluation

The sustainability evaluation has been proposed by Odum [62], which is an emergy analysis. The emergy is “the available energy of one kind previously used up directly and indirectly to make a product or service.” Every material, energy, monetary, and manpower are counted in this analysis, which will transform into the same unit. The transformity or unit emergy value (UEV) was used to convert all stream into emergy flow (sej/Y). This analysis result would reveal both economic and environmental impact. The emergy indices including of; unit emergy value (UEV), environmental loading ratio (ELR), emergy yield ratio (EYR), and emergy sustainability index (ESI).

#### 3.3.4.4.1. UEV, Unit emergy values

$$UEV_S = \frac{\text{Total Emergy flow}}{\text{Emergy flow, Products flow, Service}} \quad (3.3.5)$$

UEV is a transforming factor calculated from the ratio between the total energy and energy flow product and service, as shown in Eq. 3.3.5. In a good case, UEV is low. The low UEV indicates the low total energy flow for producing one unit of product. [62] This transformity makes the difference between economic and energy analysis. Economics takes everything into account by the price, which is indicated by the human need. However, the energy flow indicates all the solar energy used to produce the products, energy or service. Accordingly, the energy analysis will represent a more reasonable result than economic. In addition, the UEV is used to transform all of the energy streams into one form of solar energy (sej).

#### 3.3.4.4.2. ELR, Environmental loading ratio

ELR is the environmental loading ratio, representing the loading of the process to the environment, as shown in Eq. 3.3.6. In a good case, ELR should low. When ELR is close to 2, it is low environmental loading. When ELR between 3-10, it is a moderate level of environmental loading. Finally, when ELR is more than 10, the environmental loading is high level [63].

$$ELR = \frac{N+F}{R} \quad (3.3.6)$$

Note that

N = local non- renewable resource; natural gas.

R= local renewable resource; water, air.

F = expense cost, external goods, Ni, Na<sub>2</sub>CO<sub>3</sub>, Al<sub>2</sub>O<sub>3</sub>, equipment, labor cost.

#### 3.3.4.4.3. EYR, Energy yield ratio

EYR is energy yield ratio which it indicates competitive ability in the economic and the stability of the process. EYR is calculated from the total energy flow divided by the energy of expense goods (F), as shown in Eq. 3.3.7. In the good case, EYR is high. The reason for high EYR is low F. It represents that the process hardly relies on external resources. When the process relies on the internal resource, the process will provide high stability, which is a highly competitive ability in the economy. In the good case, EYR is high, but, in the worst case, EYR is equal to 1.

Moreover, when EYR is lower than 2, it indicates that the process is not suitable to be an energy source by the study of Ulgiati and Brown. [29]

$$EYR = \frac{\text{Total energy}}{\text{External resources}} = \frac{R+N+F}{F+L} \quad (3.3.7)$$

#### 3.3.4.4.4. ESI, Emergy sustainability index

ESI is emergy sustainability index that indicates the sustainability of the process. It is calculated from the ratio of EYR to ELR, as shown in Eq. 3.3.8. It is the ratio of profit to the loading of the environment. When ESI is lower than 1, the process is not long-term sustainability. When ESI is lower than 1, the process is not long-term sustainable. When ESI is 1-5, the process is medium sustainability. Finally, when ESI is higher than 5, the process is long-term sustainable

$$ESI = \frac{EYR}{ELR} \quad (5.8)$$

## Chapter 4

### Investigation of parameters of the HAT cycle in CLC for power production.

#### 4.1 Research gaps

The limitation of previous studies of the CLC study is the investigation of each parameter individually. However, the synergistic effects among parameters in the system were not considered. In this study, the  $3^k$  factorial design is used for solving this problem and systematically indicating their interaction. In this study, four independent input variables, which were the pressure of air reactor, number stages of air compressors, methods of air compression, and airflow rate on the lower heating value (LHV) efficiency or thermal efficiency, were studied. There are also four responses to be observed, which consist of thermal efficiency, power production from air reactor, work of air compressors, and air compressor discharge temperature. The HAT cycle included the multi-stage compressor, heat exchanger for intercooler between compressors and turbines. Accordingly, the operation of the HAT cycle is directly relating to the work consumed by all compressors and the work produced by the turbines. The  $3^k$  factorial experimental result can reveal the effects and the curvature interactions of operating parameters, which leads to high thermal efficiency. The advantages of this study are obtaining the operating condition for the highest thermal efficiency of CLC with the HAT cycle process.

#### 4.2 Objective

To study the effects of HAT operation conditions on power production with the chemical looping combustion process.

#### 4.3 Results and discussion

This investigation aimed to identify the operating condition that reaches the highest thermal efficiency of CLC with the HAT cycle system. The  $3^k$  factorial experimental design was selected for investigation. There were 81 cases in total to be simulated and evaluated the outputs. The values of these four input variables which were used in the study were shown in Table 4.1. Furthermore, the detail of each case study was shown in Table 4.2.

**Table 4.1** The values of four parameters conducted in  $3^k$  factorial experiment.

Variable	Name	Units	Low value	Middle value	High value

In this study, the four individual input parameters have investigated the effect on the four responses. The four parameters were the pressure of the air reactor, the number of air compressor stages, method of air compression, and airflow rate. The four responses were thermal efficiency consist of thermal efficiency, power production from air reactor, work of air compressors, and air compressor discharge temperature. All of the parameters were systematically conducted to express the relation of all operations in the system. In Table 4.2, the highest thermal efficiency was case 81, which obtained 55.87% of thermal efficiency and 503.88 MW of power production. Case 16 had a minimum of compressor workload, but there was only 48.67% thermal efficiency.

Furthermore, the operation to achieve the low-temperature air compressor outlet led to low compressor work, but there was 48.23% thermal efficiency. The analysis from this study would express the relation of operation that represents a good understanding of CLC with the HAT cycle system, which it was not straightforward to choose the operating conditions. The effect of the parameters on the responses which was expressed in the next section.

#### **4.3.1 The effect of operating parameters on the thermal efficiency**

The high thermal efficiency indicated the high worthiness of the fuel used for power production. The result of variance analysis (ANOVA) indicated that A, C, and AC had affected thermal efficiency since their p-values were lower than 0.05, as shown in Table 4.3. The pressure of air compressor (A), compression method (C) and the interaction between the pressure of air compressor and compression method (AC) had an impact on thermal efficiency. The simulation showed that the pressure of air compressor (A) and compression method (C) significantly affected thermal efficiency shown by the high slope, as shown in Fig. 4. 1. Nevertheless, the number of compressors (B) and airflow rate (D) had less impact on thermal efficiency in this range, as shown in Table 4.1. Case 81 achieved the maximum thermal efficiency of 55.875% at 15 atm, 7 stages, method 3, and 61000 kmol/hr. Case 39 obtained the minimum thermal efficiency of 45.388% at 15 atm, 3 stages, method 2, and 59,500 kg/hr. The case studies that obtained thermal efficiency higher than 55% were case numbers 21, 24, 27, 48, 51, 54, 75, 78 and 81. These cases operated at 15 atm of pressure and compression method 3, but the number of compressors and airflow rates differed.

Case 75 shows an interesting result. Its thermal efficiency was slightly lower than case 81, with a value of 55.84%. The difference between case 75 and case 81 was the number of air compressor stages in which there were 3 and 7 stages, respectively. The increase of the stage of air compressor led to the increased unit of an intercooler between compressor stages. However, the increase up to 7 stages to gain 0.03% higher in thermal efficiency was not worthwhile for investment. The operation condition of the cases 75 and 81 were 15 atm of air reactor pressure, method 3 of air compression, and 61,000 kmol/hr of airflow.

The thermal efficiency was calculated from the net power production divided by the lower heating efficiency of fuel. In this case, the natural gas was the fuel, as shown in Eq. 4.1.

*Thermal efficiency (%) =*

$$\frac{\text{Power production from AR and FR (kW)} - \text{Work of compressor (kW)} - \text{Work of water pump (kW)}}{\text{Lower heating value of fuel (kW)}} \times$$

$$100 \quad (4.1)$$

The effect of air reactor pressure and compression method for air compressors on thermal efficiency is shown in Fig. 4.2. Method 3 reached the highest thermal efficiency, followed by method 2 and method 1, respectively. In method 3, the compression ratio of the last compressor stage was higher than the others. It led to the highest temperature of the outlet stream. After this stream was preheated, it was introduced to the air reactor, which led to increased air reactor temperature. The outlet of the air reactor would be finally sent to produce power at the turbine. Accordingly, the increase in air compressor pressure would be why the increase in power production and thermal efficiency, as shown in Table 4.4. On the other hand, the

compression ratio at the last stage in method 1 was the lowest. The temperature of compressor discharge would be the lowest. It was the reason for low power production and low thermal efficiency. The compression ratio of method 2 was lower than method 3 but higher than method 1. Accordingly, method 3 requires the highest work, method 2 require the least work and method 1 is in the middle of the two methods. For method 2 and method 3, the increase of air reactor pressure from 5 to 15 atm increased thermal efficiency. In method 1, the increased pressure from 5 to 10 atm increased thermal efficiency, but thermal efficiency decreased when pressure was increased to 15 atm. Simultaneously, the increase in temperature discharge would increase the water flow rate into the system. However, the increase of pressure led to a decrease in water flow rate. Method 3 brought about the highest temperature discharge of the air compressor. Subsequently, the water was fed into the system more than other methods. At the same method, the increase of pressure was higher thermal efficiency than the increase in temperature. The pressure discharge of the turbine was 1 atm. When the pressure inlet increase, the temperature discharge from the turbine would decrease. Because the outlet stream from the turbine was used to preheat other streams, the decrease in temperature discharge from the turbine would decrease the total heat recovery. Water would be fed lower into the system, as shown in Table 4.4. Thereby, the increase in pressure would decrease the water flow rate of the system.

**Table 4.4** The temperature discharge of air compressor, water flow rate and temperature discharge of air turbine.

Case	Pressure (atm)	Method of air compressor	Temperature discharge of air compressor (°C)	Water flow rate (kg/hr)	Temperature discharge of air turbine (°C)

Fig. 4.1 The effect of main operating parameters on thermal efficiency.

Fig. 4.2 The effect of pressure of air reactor and air compression method on thermal efficiency.

#### 4.3.2 The effect of operating parameters on the power production from air reactor

The increase in power production would increase thermal efficiency, as shown in the thermal efficiency equation. In this study, the air reactor's power production

was focused because it produced high power production than the fuel reactor's power production. The power production from the air reactor was 503.88 – 347.07 MW, but that from the fuel reactor was 77.8 MW. In this study, the power production from the air reactor was selected as a response. The four input parameters were exactly affected by power production from the air reactor. The power production from the fuel reactor was not significantly affected, as shown in table 4.2.

The variance analysis in Table 4.5 indicated that pressure of air reactor (A), compression method (C), airflow rate (D), and the interaction between the pressure of air reactor and compression method (AC) affected the response parameter since their p-values were lower than 0.005. Case 75 achieved the maximum power production at 15 atm, 3 stages, method 3, and 61,000 kmol/hr. On the other hand, case 7 achieved the minimum power production at 5 atm, 7 stages, method 1, and 58,000 kmol/hr. Even though case 75 was the maximum power production, it was not the highest thermal efficiency. However, case 75 reached the 2<sup>nd</sup> highest thermal efficiency, which inferior to case 81. The increase of air reactor pressure highly affected power production because the slope was higher than the other, as shown in Fig. 4.3. The increase in airflow rate increased power production. Method 3 produced power more than the other methods, as shown in Fig. 4.4.

**Table 4.5** The ANOVA for the power production from the air reactor

Fig. 4.3 The effect of main operating parameters on power production from the air reactor.

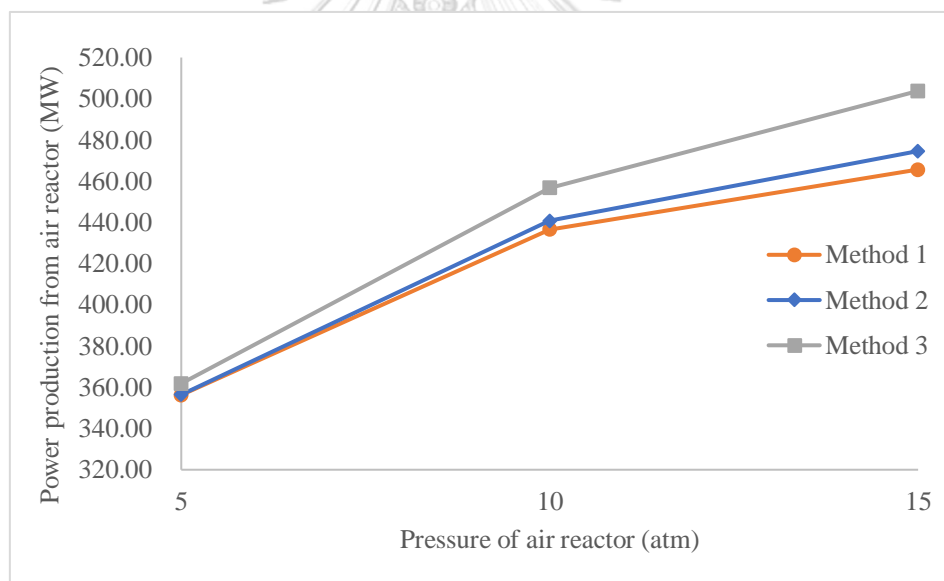

Fig. 4.4 The effect of pressure of air reactor and air compression method on the power production from air reactor.

Fig. 4.5 The effect of pressure of air reactor and air compression method on temperature discharge of turbine (TURB-101).

For all air compression methods, the air reactor's pressure was increased the power production from the air reactor. Especially for the combination of the method of air compression and the pressure level, the combination between method 3 and the high-pressure level provided the highest power production of all combinations, as shown in Fig. 4.4. Besides, this combination brought about the highest temperature discharge from the turbine (TUR-101), as shown in Fig. 4.5. The operation of method 3 was the reason for the highest temperature of air compressor discharge obtained.

The sequence of compression ratio was different in each method of air compression operation. Table 4.6 shows the compression ratio in each stage for all compression methods. The high compression ratio led to the high temperature and pressure discharge of the compressor, which provided the high work consumption of the air compressor. There was an intercooler for transfer heat from the compressed air to the cooling water. The compression ratio of method 1 was highest in the first stage. Therefore, the majority of heat in the air compression process was released into the cooling water. While the compression ratio of method 3 was highest at the last stage, the discharge temperature of method 3 was higher than case 1. This reason provided the air reactor's higher temperature, which led to high power production when method 3 was selected for operation.

**Table 4.6** The compression ratio for 5 stages at the highest level (20 atm)

	Stage 1	Stage 2	Stage 3	Stage 4	Stage 5
Method 1	13.00	1.114	1.114	1.114	1.114
Method 2	1.821	1.821	1.821	1.821	1.821
Method 3	1.114	1.114	1.114	1.114	13.000

Fig. 4.6 The effect of air flow rate on the power production from the air reactor.

The high temperature discharge from the air compressor would increase the air reactor's temperature and increase power production from the air reactor. Accordingly, the synergistic effect from the high-pressure level and the suitable compression method was the reason for the high-power production. The increase of the air flow rate into the system increased power production from the air reactor because it increased working fluid into the turbine, as shown in Fig. 4.6. The turbine's power production was affected by the pressure and temperature of the introduced stream to the turbine. The increase in power production resulted from the high pressure, high temperature, and high mass flow rate of the introduced stream to the turbine.

On the other hand, the combination of Method 1 and the lowest level of air reactor pressure provided the low power production from the turbine. The suitable

operation of pressure level, compression method, and the airflow rate caused the high mass flow rate of water. Water would be introduced into the system as much as the fuel reactor's temperature was not lower than 1,350°C, as shown in Table 4. 4. Accordingly, the suitable condition led to an increase in the working fluid of the turbine in which air and water were the working fluid in this system.

The decrease in water flow rate would directly affect power production, as shown in Table 4.7. For dissection, there were 4 additional cases simulated. The water flow rate of those cases was decreased to 90%, 80% and 70% from case 81. The 30 MW of power production decreased when the water flow rate was decreased. The thermal efficiency also decreased from 55.875% to 51.036% as well. Nevertheless, the compressor's work slightly increased because the water was used in cooling down the compressed air. The decrease in water flow rate led to increased compressed air temperature and the workload of the compressor.

**Table 4.7** The effect of water fed to air reactor and turbine on the power production and efficiency of the system

% Water flow rate of case 81	Water flow rate (kg/hr)	Power production from air reactor (MW)	Thermal efficiency (%)	Work of compressor (MW)
100%	275,252	503.79	55.875	197.18
90%	247,726	493.33	54.29	197.67
80%	220,201	482.71	52.673	198.2
70%	192,676	472.01	51.036	198.79

### 4.3.3 The effect of operating parameters on the work consumption of compressors

The decrease in compressor's work would increase thermal efficiency. The HAT cycle was applied to the system to decrease the work consumption of the compressors. All of the parameters that were investigated in this study completely affected to workload of the compressor. The work of compressor highly consumed power which was about 25.8 - 44.8% of total power production, as shown in Table 4.6. Accordingly, studied the effect of compressor's work was significant for investigation. The variance analysis in Table 4.8 indicated that pressure of air reactor (A), a number of the compressors (B), compression method (C), the air flow rate (D),

the interaction between the pressure of air reactor and compression method (AC), the interaction between pressure of air reactor and the air flow rate (AD), and the interaction between a number of the compressors and compression method (BC) had impacts on the compressor's work, since their p-values were lower than 0.005.

**Table 4.8** The ANOVA for the work of the compressor

	Sum of		Mean	F	p-value	
Variables & Interaction	Squares	Df	Square	Value	Prob > F

BD	2.57	4	0.64	0.72	0.5836	
CD	3.90	4	0.97	1.09	0.3729	
Residual	42.96	48	0.89			
Cor Total	119017.55	80				

The increase in air reactor pressure highly increased the compressor's work, as shown by the high slope of response curves in Fig. 4.7. The increase in the airflow rate increased the work of the compressor. Method 2 of compression operation brought about the lowest compressor's work, but Method 1 and Method 3 reached the higher work consumption of air compressors. The heat releasing from compressed air in method 2 was better than other methods because the heat was evenly released from each compressor. The heat releasing from compressed air by other methods was lower than method 2. The reduction of compressed air temperature within multi-stage compressors decreased their work, which method 2 provided this suitable operation for the compressor. In case 16, method 2 was operated and achieved the minimum work requirement, as shown in Fig. 4.8. The lowest workload of the compressor was achieved from the minimum airflow rate, but it led to lower power production and low system efficiency.

Method 3 operated with the highest compressor work, as shown in Fig. 4.8 – 4.9. The highest workload of the compressor brought about the

high temperature outlet from the air compressor. Then, the high temperature stream was introduced into the air reactor and increased the air reactor's temperature, power production, and thermal efficiency.

The increase in the number of compressors decreased the work of compressors, as shown in Fig. 4.9. The 7 stages of compressor obtained the lowest compressors' work while the 3 stages of compressor obtained the highest compressors' work. Accordingly, the increase of stages of the compressor decreased the work of the compressor. The increase in compression stages highly affected only method 2, as shown in Fig. 4.9. Even the increase of the compression stage did not highly affect the power of the compressor; the single-stage compressor consumed the highest work, as shown in Fig. 4.10. The increase of compressor stages highly affected the power of the compressor at a high-pressure level. The increase of the air flow rate and pressure of the air reactor would increase the work of compressors. The high air flow rate and the air reactor's high pressure would increase the work of the compressor. On the other hand, the low air flow rate and the air reactor's low pressure decreased the work of compressors, as shown in Fig. 4.11. The best case for operating the compressor would likely be with a lower power requirement. Case 16 showed the minimum compressor work, 89.636 MW, operated at 5 atm, 7 stages, method 2, and 58,000 kmol/hr. Case 75 showed the maximum compressor work, 197.490 MW, operated at 15 atm, 3 stages, method 3, and 61,000 kmol/hr. The thermal efficiency of case 16 was 48.672%, but that of case 75 was 55.843%. The work of compressor and thermal efficiency in case 81 was 197.179 MW, and 55.875%. The compressor work in case 81 and case 75 were 2 times higher than case 16. Thus, the operating conditions which low compression consumption did not enough to achieve the high system efficiency.

#### 4.3.4 The effect of operating parameters on the discharge temperature of air compressor

The effect of temperature discharge of air compressors on power production was barely investigated in the CLC system. This parameter directly affected power production and thermal efficiency, as well. The high discharge temperature of the air compressor increased the air reactor temperature. The outlet stream from the air reactor would be sent into the turbine for power production after it was preheated. The high temperature inlet to the turbine would increase the power production and thermal efficiency of the system. Accordingly, this parameter was a significant parameter to achieve high thermal efficiency. The variance analysis in Table 4.9 indicated that the parameters affected the discharge temperature of the air compressor. These parameters were air reactor pressure ( A ) , the number of compressors ( B ) , compression method ( C ), the interaction between air reactor pressure and the number of the compressors ( AB ), the interaction between air reactor pressure and compression method ( AC ) , and the interaction between the number of compressors and compression method ( BC ).

**Table 4.9** The ANOVA for the discharge temperature of the air compressors

Source	Sum of Squares	Df	Mean Square	F Value	p-value Prob > F	
A-Pressure of air reactor	244847.52	2	122423.76	2787.98	< 0.0001	significant
B-Number of compressors	2526.75	2	1263.37	28.77	< 0.0001	significant

CD	96.25	4	24.06	0.55	0.7013	
Residual	2107.74	48	43.91			
Cor Total	505688.07	80				

Fig. 4.12 The effect of the main operating parameters on the discharge temperature of the air compressor.

The increase of air reactor pressure extremely increased the air compressor's discharge temperature, as shown in Fig. 4.12. The decrease in the number of compressors highly decreased the air compressor's discharge temperature because it was high slope also. The increase of the number of air compressors would increase the units of inter-cooler that were installed between stages of compressors. The high

units of inter-cooler led to high heat releasing from the compressed air. The discharge temperature would be decreased. The effect of the number of compressors on temperature discharge from air compressors highly affected method 2 of compression operation, as shown in Fig. 4.13. Method 3 was the best compression operation to reach the highest discharge temperature, as shown in Fig. 4.13. The increase in the number of air compressors in method 1 and method 3 did not affect discharge temperature. The high heat source in method 1 and method 2 were the first and the last compressors. Accordingly, the heat in the system operated with method 1 and method 3 was not well transfer. The increase in the number of compressors highly affects at a high-pressure level, as shown in Fig. 4.14. The compressor operation highly affected the air compressor's discharge temperature, as shown in Fig. 4.12. Furthermore, the compression method in method 3 at high pressure achieved the highest temperature discharge, as shown in Fig. 4.15. The combination of method 1 for compression operation with low-pressure level obtained the lowest temperature discharge.

Case 75 obtained the highest discharge temperature of air compressor, 399.36°C at 15 atm, 3 stages, method 3, and 61,000 kmol/hr. On the other hand, case 7 obtained the lowest discharge temperature of air compressor, 136.03°C at 5 atm, 7 stages, method 1, and 61,000 kmol/hr. For these two cases, there was a trend of discharge temperature and power production. In case 75, the highest discharge temperature led to the highest power production. On the other hand, the lowest discharge temperature, case 7, led to the lowest power production case. From this analysis, the operation condition for obtaining the high temperature discharge was also selected for high power production achievement.

#### 4.4 Further efficiency improvement

The proportion of Ni loading was investigated because it affected the temperature of the air reactor which influenced to the power production from the air reactor and thermal efficiency, in the end. The loading of Ni on the  $\text{Al}_2\text{O}_3$  supporter was investigated in various studies. As the study of Huijun et al., the reason for the high conversion of carbon was the increase of % Ni loading [113]. In the study of Huijun et al. and Ishida et al., the high NiO loading on  $\text{Al}_2\text{O}_3$  achieved the maximum conversion of carbon and syngas in the biomass combustion process [113, 114]. The 50% of NiO loading on  $\text{Al}_2\text{O}_3$  reached the highest conversion in the biomass combustion process. However, the increase of Ni loading had not been considered the effect on power production and thermal efficiency of the system. Accordingly, the effect of Ni loading on thermal efficiency was investigated. The investigated range of Ni loading was 10-60% by mole or 6-46% by weight (wt). The highest thermal efficiency case as case 81 was selected for the investigation. In the previous section, the Ni loading of case studies was 16. The increase of Ni loading was conducted by fix the total mass flow of Ni, 908,649 kg/hr. The Ni mass flow rate was kept constant to provide complete combustion with natural gas. Therefore, the adjustment of Ni loading was the changing of  $\text{Al}_2\text{O}_3$  only. Typically,  $\text{Al}_2\text{O}_3$  had two functions. First, it

was the supporter of Ni or NiO for improving the mechanical properties of the oxygen carrier. Since, the reaction in the air reactor was exothermic and the reaction in the fuel reactor was endothermic. The temperature of air reactor was higher than fuel reactor. Consequently, the generated heat in air reactor was the heat source for the fuel reactor. Second,  $\text{Al}_2\text{O}_3$  could carry heat from the air reactor to the fuel reactor.

The increase of Ni loading provided the low  $\text{Al}_2\text{O}_3$  and the total mass of the solid. When the total mass of solid was low, the temperature of the air reactor was increased, followed by the calculation of enthalpy ( $Q = mC_p\Delta T$ ). Accordingly, the increase of Ni loading from 6% to 46%wt provided the increased temperature of the air reactor from 1,375°C to 1,625°C, as shown in Fig. 4.15.

The increase of air reactor temperature would be a cause of the high-power production of air reactor, as shown in Fig. 4.16. The increase of Ni loading from 6% to 28%wt led to the increase of power production from the air reactor because the temperature inlet to the turbine was increased.

Since the CLC process was operated with the HAT cycle which humid air was generated. The humid air was introduced to the air reactor which provided the high mass flow rate to the turbine and high-power production. When water flow rate had been decreased, the power production from the air reactor was decreased. Therefore, when the Ni loading was increased higher than 28%wt, the power production from the air reactor was decreased because the water flowrate was decreased, as shown in Fig. 4.17. In addition, the high-water flow rate provided the high-power production from the air reactor, but the temperature of the air reactor was decreased. At the high proportion of Ni loading, the solid from the air reactor was sent to fuel reactor with low mass flow rate. Therefore, the solid from the air reactor should be sent at high temperature for remain total heat supplied to the fuel reactor.

The increase of Ni load led to the increase of work consumption of compression, as shown in Fig. 4.18. Since the water flow rate was decreased. The water was introduced to the HAT cycle for 2 reasons; 1) humid air generation and 2) work consumption of air compression reduction. Water was the coolant at the intercooler. Water was received heat from the compressed air between the multi-stage compressor. The low temperature inlet to the compressor provided the low work

consumption of air compression. According, when the water flow rate of the process was decreased, the work consumption of air compression was increased.

Eventually, the thermal efficiency was increased when Ni loading was increased from 6% to 28%wt because of the increase of temperature and power production from the air reactor, as shown in Fig. 4.19. When Ni loading was higher than 28%wt, the thermal efficiency was decreased because of the increase of work consumption of air compression and the decrease of water flowrate. The suitable Ni loading could carry the fuel reactor's heat needed without external energy supplies. It would lead to optimum air reactor temperature, optimum solid temperature, optimum water mass flow rate, and high efficiency. For this process, the suitable Ni loading was 28% wt, which achieved the highest thermal efficiency of the CLC process with the HAT cycle, 57.67% at 15 atm, 7 stages, and method 3.

#### 4.5 Conclusion

This study objective is to systematically investigate the operating variables that have effects on the efficiency of the CLC combined with HAT unit to produce electricity. Both system configurations and operating conditions were simultaneously investigated. The high thermal efficiency represented the worthiness of the using of fuel. Four operating variables; pressure of the air reactor, number of air compressor

stages, methods of air compression and air flow rate were investigated their effects on four responses; the thermal efficiency, power production from air reactor, work of air compressor and air compressor discharge temperature. In this study, the maximum thermal efficiency of the CLC process with the HAT cycle was 57.67%, while that of Petriz-Prieto et al. study was 56.08% [49]. However, the result did not aim for comparison. It was used to be the preliminary data in operation for reach the high efficiency in power production and making decision for the practical operation.

For more understanding of the system, four input parameters, which were the pressure of the air reactor, the number of compressors, the compression method and the air flow rate, were investigated their effects on the four responses: the thermal efficiency, the power production from air reactor, the work of air compressor, and the discharge temperature from the air compressor. The  $3^k$  factorial design was used for investigation. Case 81 gave the maximum thermal efficiency, 55.87% , with the operation at 15 atm, 7 stages, method 3, and 61,000 kmol/hr. However, case 75 operated the same operating condition as case 81, but used only 3 stages of compression, had a thermal efficiency of 55.84% . In this case, case 75 could be a better solution since the investment cost would be lower than case 81, while the thermal efficiencies were quite the same. Thus, case 75 was selected as the base case for the CLC process with the HAT cycle.

The result showed that the increase in air reactor pressure, the number of compressors, and the air flow rate would increase the thermal efficiency. Method 3 of the compression operation led to high thermal efficiency. It was also found that air reactor pressure and compression operation methods highly affected thermal efficiency. Method 3 for compression operation reached high thermal efficiency because it brought about the highest discharge temperature for the turbine. The high discharge temperature was the reason for the high air reactor temperature, high power production from the turbine, and high thermal efficiency. The high discharge temperature was the reason for the high-water flow rate introduced into the HAT cycle. Water absorbed the heat in compressed air, causing the reduction of compression work. Therefore, a high-water flow rate was fed into the system when method 3 was operated. The increase of compression stages would increase the inter-coolers to release heat of compressed air. The operation for obtaining the high-power

production and high temperature discharge should be selected to operate more than low power consumption of air compression. At last, the amount of Ni loading in the system was studied. Since the Ni mass flow rate was constant, the increase of Ni loading was carried out by decreasing  $\text{Al}_2\text{O}_3$ . The  $\text{Al}_2\text{O}_3$  acted as a heat source for the fuel reactor. It was found that the system with 28% wt of Ni loading gave the highest thermal efficiency of 57.67%.

## **Chapter 5**

### **Hydrodynamic behavior of chemical looping combustion**

#### **5.1 Research gaps**

Chemical looping combustion could be used with solid fuel and gaseous fuel. The solid fuel would be coal and biomass, while the gaseous fuel could be natural gas. The challenges to operate the process with these fuels were different. The major challenge of solid fuel is the unburnt char because of the slow gasification rate. However, for the gaseous fuel system, the combustion was mostly complete.

Nonetheless, improper operating conditions could also lead to incomplete combustion. Its consequence is the CO<sub>2</sub> emission from the air reactor. Therefore, the operating conditions are a crucial factor in achieving suitable hydrodynamics and obtaining high thermal and CO<sub>2</sub> capture efficiencies.

#### **5.2 The objectives**

For the first section, the operating conditions were systematic investigation for suitably hydrodynamic behavior. The fuel and oxygen carriers for this section were coal and iron oxide (Fe<sub>2</sub>O<sub>3</sub>/Fe<sub>3</sub>O<sub>4</sub>).

For the second section, the operating conditions which obtained the high thermal efficiency from chapter 3 were investigated for suitably hydrodynamic behavior under chemical reactions. The fuel and oxygen carrier for this section was methane (CH<sub>4</sub>) and nickel oxide (NiO/Ni). Then, the conversion and temperature achievements would be determined.

#### **5.3 Results and discussion of the first part**

##### **5.3.1 Model validation**

When the system reached the steady-state condition, the mass fraction outlet of the reactor would fluctuate around the constant value. The result of the simulation model was collected and interpreted. The model without reaction or cold flow model was validated with the experimental data. After that, the model will include the reaction model and simulate when reactions occur.

The model was validated by running the cold flow model under isothermal at 1173 K and the coal feeding velocity at 1 m/s. The obtained solid volume fraction (VOF) contour from the simulation was compared with the experimental data studied

by Su et al. [97]. The solids in their system, including iron oxide and coal. The contours of the solid volume fraction of the model simulation and experimental data were consistent, as shown in Fig. 5.1. It represented that the VOF was dense in the downers and the VOF was well dispersed in the risers. In the hot flow model, the mass fraction outlet from the reactor was compared with the experimental data, which was studied by Su et al. [97]. The result of fuel and air reactors are shown in Fig. 5.2 and 5.3, respectively. The mass fraction outlet results between the simulation data and the experimental data were consistent. When the simulation data and the experimental data were consistent in cold and hot flow models, the model was used for further investigation because this model could represent the reasonable result of the dual circulating fluidized bed reactor (DCFBR) for the CLC process.

The interested point of this model was  $\text{CO}_2$  in the outlet of the air reactor. It occurred from the unburnt coal in the fuel reactor. In theory, the air reactor's gas composition should not consist of  $\text{CO}_2$  because the air reactor's total outlet would be directly released to the environment.  $\text{CO}_2$  contamination was the cause of the environmental crisis and it was the indicator of unsuitable operation. Consequently, the investigation of the operating condition was crucial for process improvement.

Fig. 5.3 The mass fraction of gas outlet from the air reactor

### 5.3.2 ANOVA result

The ANOVA analysis could indicate the significant parameters and the interaction of parameters on the system responses. The two input parameters consisted of the reactor's temperature (parameter A) and the ratio of coal feeding velocity to the oxygen carrier's weight (parameter B). Three levels of parameter A were 1173, 1373, 1583 K and the three levels of parameter B were 0.1/400, 0.5/400, 1.0/400 (m/s)/kg. The two responses consisted of the combustible gas percentage from the fuel reactor

and the CO<sub>2</sub> percentage from the air reactor. The result of ANOVA analysis is shown in Table 5.1 and 5.2. The two models were significant because the p-value was lower than 0.05.

**Table 5.1** The effect on the combustible gas percentage from the fuel reactor

### 5.3.3 The effect on combustible gas percentage from the fuel reactor

The combustible gas percentage from the fuel reactor was calculated from the molar flow rate of CH<sub>4</sub>, C<sub>2</sub>H<sub>6</sub>, H<sub>2</sub>, and CO from the fuel reactor's outlet divided by the total molar flow rate of the fuel reactor. The high percentage indicated low performance. The ANOVA result in Table 5.1 represented that the temperature (A) and the ratio of coal velocity to the oxygen carrier's weight (B) affected the combustible gas percentage from the fuel gas since the p-value was lower than 0.05. The increase of A and B caused an increase in the combustible gas species, as shown in Fig. 5.4.

The reaction in the fuel reactor was endothermic. [76, 115] The increasing temperature provided a higher rate of gasification reaction. Accordingly, the products of gasification were increased. The combustible gas, which included CH<sub>4</sub>, CO, and H<sub>2</sub>, were increased. [76] The increase in temperature would push the reaction forward. When the combustible gas was highly increased, the gas conversion in the fuel reactor's riser was decreased because the total solid was constant. Nonetheless, the result showed that the increase in temperature increased the combustible gas. The

increase of temperature was not only pushed the reaction forward but also increased the gas velocity in the riser. The high gas velocity decreased the residence time of the reactants in the riser and decrease the reaction between the oxygen carrier and gas reactants.

The increase of this ratio provided the high amount of coal in the reactor. This was because the oxygen carrier's weight was fixed while the coal amount was varied. When coal was introduced into the reactor, coal was gasified by the gasifier medium ( $\text{CO}_2$ ). The gas species were the products of coal gasification. After that, the gas species was reacted with the oxygen carrier. The coal then excessed. Eventually, the increase of this ratio would increase gas species in the fuel reactor because the gasification rate was increased when the temperature was increased. [76]

The best case was case 1, with the lowest value of the combustible gas. In case 1, the temperature and the ratio of coal velocity to the oxygen carrier's weight were at the lowest values of 1173 K and 0.00025, respectively. In contrast, the worst case was case 9, with the highest value of the combustible gas. In case 9, the temperature and the ratio of coal velocity to the oxygen carrier's weight were at the highest values of at 1573 k and 0.00250, respectively.

Fig. 5.4 The effect on the combustible gas from the fuel reactor

### 5.3.4 CO<sub>2</sub> percentage from the air reactor

The CO<sub>2</sub> percentage from the air reactor was calculated from the molar flow rate of CO<sub>2</sub> from the air reactor's outlet divided by the total molar flow rate from the air reactor. The high percentage indicated low performance. The ANOVA result in Table 5.2 indicated that the ratio of coal velocity to the weight of the oxygen carrier (B) and the relationship of temperature and the ratio of coal velocity to the weight of the oxygen carrier (AB) affected CO<sub>2</sub> percentage from the air reactor since their p-value was lower than 0.05. The increase of B and AB caused the increase of the CO<sub>2</sub> from the air reactor, as shown in Fig. 5.5.

After coal was gasified, the process produced gas products and char. The unburnt char from the fuel reactor was transferred to the air reactor. At the air reactor, the air was oxidized with the metal to produce an oxygen carrier. When the unburnt char was transferred to the air reactor, the char was oxidized by O<sub>2</sub> in the air. CO<sub>2</sub> was produced and contaminated in the excess air, which was directly released into the environment. The high ratio of coal velocity to the oxygen carrier's weight led to high introduced coal in the reactor, which increased the unburnt char in the fuel reactor, as shown in Fig. 5.5.

When the reactor was operated at high temperature and high ratio of coal velocity to the oxygen carrier's weight, the gas velocity and coal were high, which led to the high unburnt char in the fuel reactor.

The increase in temperature provided the rate of gasification reaction. Accordingly, the products of gasification were increased. The gasification products, CH<sub>4</sub>, CO, H<sub>2</sub>, CO<sub>2</sub>, and char were increased. [76] The excess gasification products, especially the unburnt char in the fuel reactor, were sent to the air reactor. Eventually, it led to the high CO<sub>2</sub> at the air reactor.

The best case was cases 1- 3 with the lowest values of the CO<sub>2</sub> from the air reactor. In these cases, the ratio of coal velocity to the oxygen carrier's weight was the lowest at 0.0025. In contrast, the worst case was cases 7-9 with the highest values of the CO<sub>2</sub> from the air reactor. The ratio of coal velocity to the oxygen carrier's weight was at the highest value of 0.00250.

Fig. 5.5 The effect on the CO<sub>2</sub> combustible gas from air reactor

### 5.3.5 Conclusion of the first section

The high performance of the CLC process was provided by suitable hydrodynamic behavior. The high performance of the CLC process led to good CO<sub>2</sub> capture efficiency. In this section, the hydrodynamic behavior of DCFBR was systematically investigated by the 2<sup>k</sup> factorial experimental design. There were two input parameters; the temperature of the reactor and the ratio of coal velocity to the oxygen carrier's weight. This systematic investigation would include the curvature behavior of the result to obtain the optimum operating condition. There were two responses; the combustible gas percentage from the fuel reactor and the CO<sub>2</sub> from the air reactor, which directly indicated this reactor performance. The result showed that the low temperature (1,173 K) and the low ratio of coal velocity to the weight of oxygen carriers (0.00025) provided the best performance of this system.

## 5.4 The results and discussion of the second section

In this section, methane (CH<sub>4</sub>) was used as the fuel and NiO/Ni was used as the oxygen carrier.

### 5.4.1 The hydrodynamics of cold flow

After model validation from the last section, the model was further used to investigate the CLC process, but the fuel and oxygen carriers were changed. The CH<sub>4</sub> was used as the fuel and NiO/Ni with Al<sub>2</sub>O<sub>3</sub> was used as the oxygen carrier. In the

first step, the cold flow model was performed for suitable hydrodynamics behavior achievement.

At the inlet of the fuel reactor riser,  $\text{CH}_4$  and  $\text{CO}_2$  were introduced into the riser.  $\text{CO}_2$  was introduced to keeping suitable hydrodynamic behavior and reduce the total amount of  $\text{CH}_4$  using in the system. At the inlet of the air reactor riser, the humid air was introduced into the riser. The humid air was used to follow the operating condition from the chapter 4 result.  $\text{NiO/Ni}$  and  $\text{Al}_2\text{O}_3$  were used as the active metal and the support followed the chapter 4 result. The optimum Ni loading on  $\text{Al}_2\text{O}_3$  was 40%mol, which convert into %mass

There were 2 values of the initial solid volume fraction; 0.35 and 0.45, which were studied. The simulation data indicated that the flow direction was correct. The solid volume fraction was dense in the downers. The solid was well dispersed in the riser. The increase of the initial solid volume fraction would increase the solid volume fraction in the downers. The contour of the solid volume fraction is shown in Fig. 5.6. It was not found the reverse flow from the riser inlet to the loop-seal. The solid was dense at the loop-seal. Therefore, it would block the inlet gas, which flowed through the downer. The reverse flow led to the low performance of the reactor and low  $\text{CO}_2$  capture efficiency. In the cold model, the initial temperature was 873 K. The temperature contour was slightly different because the density of the mixture was changed. The temperature contour of the initial solid volume fraction at 0.35 and 0.45, as shown in Fig. 5.7 and Fig. 5.8, respectively. The gas temperature profile was slightly higher than the solid temperature. The mixture of gas density directly affected the temperature because the mixture of gas was calculated by the volume-weighted-mixing-law method. With this method, the high change of gas composition would be the reason for gas density and gas temperature. The composition of the solid phase was not highly changed. Therefore, the change of solid temperature was low.

Fig. 5.8 The temperature contour of the gas phase (left) and solid phase (right) at initial VOF 0.45

### 5.1.1. The hydrodynamics of hot flow

After the cold flow model was completely investigated, the model was proven that the boundary and the setup of significant input data were satisfied for suitable hydrodynamic behavior of the cold flow. The data of the cold flow model at the 20 seconds was used to perform in the hot flow model. For the hot flow model, the reaction of Ni and O<sub>2</sub> in the air reactor and the reaction of CH<sub>4</sub> and NiO in the fuel reactor were included, as shown in Eqs. 5.1 and 5.2, respectively.

The activation energies of these equations from the study of Abad et al. were adjusted to 7 kJ/mol for all reactions. [102] There were four investigated parameters; rate reaction, initial solid volume fraction, velocity, and CH<sub>4</sub> mass fraction in the feed. The parameters were adjusted to obtain a suitable conversion and temperature, as

shown in Table 5.3. The simulation data was validated with the temperature, CH<sub>4</sub> conversion, and MW thermal from the experimental data. The caution for the hot flow model is the properties of the material in the system. The heat of heterogeneous reaction is the heat source of the system. The heat of the heterogeneous reaction in the air reactor (reaction 5.1) should be a positive value because it was the exothermic reaction. The heat of the heterogeneous reaction in the fuel reactor (reaction 5.2) should be a positive value because it was the endothermic reaction. When the heat of heterogeneous reaction was incorrect, the heat of formation of the material was checked. Besides, the rate exponent of the reaction was checked to obtain the responses' accuracy (temperature conversion).

**Table 5.3** The total cases study from 3<sup>k</sup> factorial experimental design and the results.

Case	Temperature (K)	V <sub>coal</sub> to weight of OC (m/s)/(kg)	% Combustible gas species from FR	%CO <sub>2</sub> from AR
1	1173	0.00025	13.15	1.84
2	1373	0.00025	16.94	1.97
3	1573	0.00025	24.48	1.80
4	1173	0.00125	16.34	2.97
5	1373	0.00125	31.96	6.93
6	1573	0.00125	47.38	9.12
7	1173	0.0025	29.68	36.47
8	1373	0.0025	51.68	36.30
9	1573	0.0025	53.64	36.71

### 5.1.1. The validation with experimental data

The results of the hot flow model are shown in Table 5.4 and Table 5.5. The conditions of all case studies were compared with the other studies investigating the hydrodynamics of the CLC reactor. The fuel reactor temperature validated with experimental data included cases 1-10, as shown in Fig. 5.9. The air reactor temperature validated with experimental data included cases 5-10, as shown in Fig. 5.9. The CH<sub>4</sub> conversion validated with experimental data included case 7, as shown

in Fig. 5.10. The thermal energy that was produced by the reactor at 1.5 m was 0.225 MW thermal. [97] The thermal energy that was produced from this study were 0.27-0.97. The thermal energy that was validated with experimental data included cases 1-10. The conditions of case 7 were  $1E+5$  of pre-exponential factor, 0.45 of the initial VOF, 1 time of velocity compared with the base case, and 0.05 of  $CH_4$  mass fraction. Accordingly, the results were confirmed that the operating conditions were realistic with the experiment. In the next section, the effect on temperature and conversion were represented.

**Table 5.4** The output conditions from the adjusted parameters

Cases	Average Temp Solid AR (K)	Average Temp Gas AR (K)	Average Temp Solid FR (K)	Average Temp Gas FR (K)

Fig. 5.10 The CH<sub>4</sub> and O<sub>2</sub> conversion of all case studies.

### 5.4.2 The effect of rate reaction

The pre-exponential reaction rate factor was the constant (A) in the Arrhenius equation, as shown in Eq. 5.3. The increase in this factor led to an increase in rate reaction.

$$k = Ae^{E_a/RT} \quad (5.3)$$

When the initial solid volume fraction was adjusted to 0.35, the pre-exponential factors in Eqs 4.1 and 4.2, were adjusted to 1, 1E+3, and 1E+5. The increase of the pre-exponential factor was why the higher conversion of CH<sub>4</sub> and O<sub>2</sub> obtained, as shown in Fig. 5.11. When the pre-exponential factor was increased from 1 to 1E+5, the conversion of O<sub>2</sub> was almost completely converted. The O<sub>2</sub> conversion was increased when the pre-exponential factor was increased. The O<sub>2</sub> conversion was the highest at the pre-exponential factor of 1E+3.

The result of the temperature in the air reactor and fuel reactor was shown in Fig. 5.12. When the pre-exponential factor was 1, the temperature of air and fuel reactors was not highly changed from the beginning condition. At the beginning condition, the temperature of all materials in the reactor and feed was 800 K. The high conversion led to high temperature in the air reactor and low temperature of fuel reactor because the reactions were exothermic and endothermic in air and fuel reactors, respectively. Therefore, the temperature in the air reactor was increased. At the pre-exponential factor of 1E+3, the fuel reactor's temperature was the lowest because the CH<sub>4</sub> conversion was the highest. At the pre-exponential factor of 1E+5, the fuel reactor's temperature was high because the temperature of the air reactor was high. In the CLC reactor, the heat was carried by the oxygen carrier from the air reactor to the fuel reactor. Accordingly, the air reactor's high temperature led to high temperatures in the fuel reactor.

Fig. 5.11 The conversion of CH<sub>4</sub> and O<sub>2</sub> when the initial VOF was 0.35

Fig. 5.12 The temperature of the air reactor and fuel reactor when the initial VOF was 0.35

When the initial solid volume fraction was changed to 0.45, the increase of the pre-exponential factor was why the higher conversion of CH<sub>4</sub> and O<sub>2</sub> obtained, as shown in Fig. 5.13. When the pre-exponential factor was increased from 1 to 1E+5, the O<sub>2</sub> and CH<sub>4</sub> conversion were increased. The high conversion led to a high temperature of reactors, as shown in Fig. 5.14.

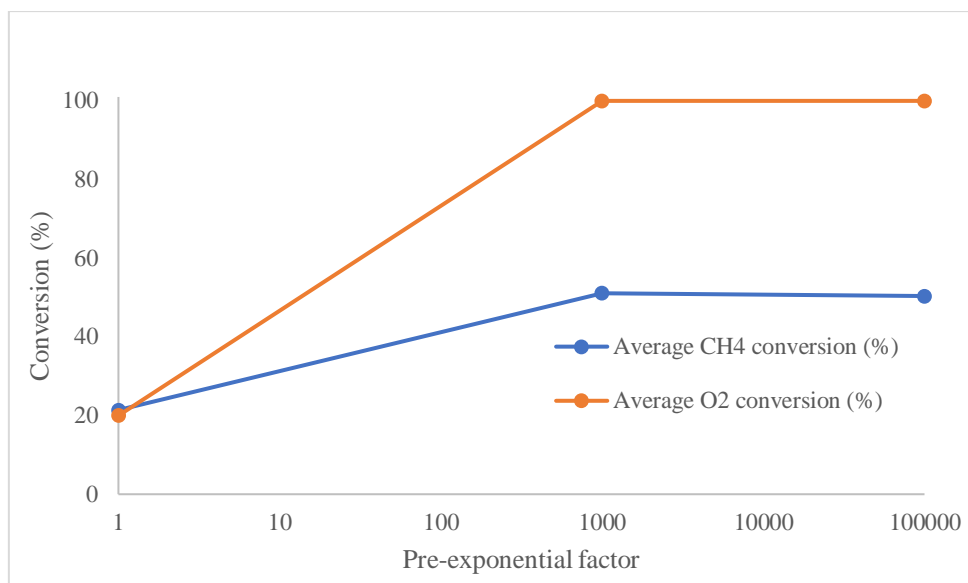

Fig. 5.13 The conversion of CH<sub>4</sub> and O<sub>2</sub> when the initial VOF was 0.45

Fig. 5.14 The temperature of air reactor and fuel reactor when the initial VOF was 0.45

### 5.4.3 The effect of the initial solid volume fraction

The initial solid volume fraction (VOF) was used at 0.35 and 0.45. The high initial solid volume fraction indicated the high total solids in the system. The total amount of solid, when initial VOFs were at 0.35 and 0.45, were 39.03 kg and 50.18 kg, respectively. The high amount of solid would be the reason for high conversion, but too much solid would fall into the bottom of the downer, as shown in Fig. 5.15.

Accordingly, too much solid in the system led to low conversion. The higher cluster was found in the riser when the initial VOF was 0.45. Accordingly, the mixing when the initial VOF was 0.35 was better.

Fig. 5.15 The volume fraction contour of the initial VOF 0.35 (left), and the initial VOF was 0.45 (right)

The conversion of  $O_2$  when the initial VOF at 0.35 and 0.45 was almost complete combustion. The increase of the initial VOF from 0.35 to 0.40 led to a decrease of  $CH_4$  conversion, as shown in Fig. 5.16. The high conversion of  $O_2$  provided the air reactor's high temperature, and the high conversion of  $CH_4$  provided the low temperature of the fuel reactor, as shown in Fig. 5.17.

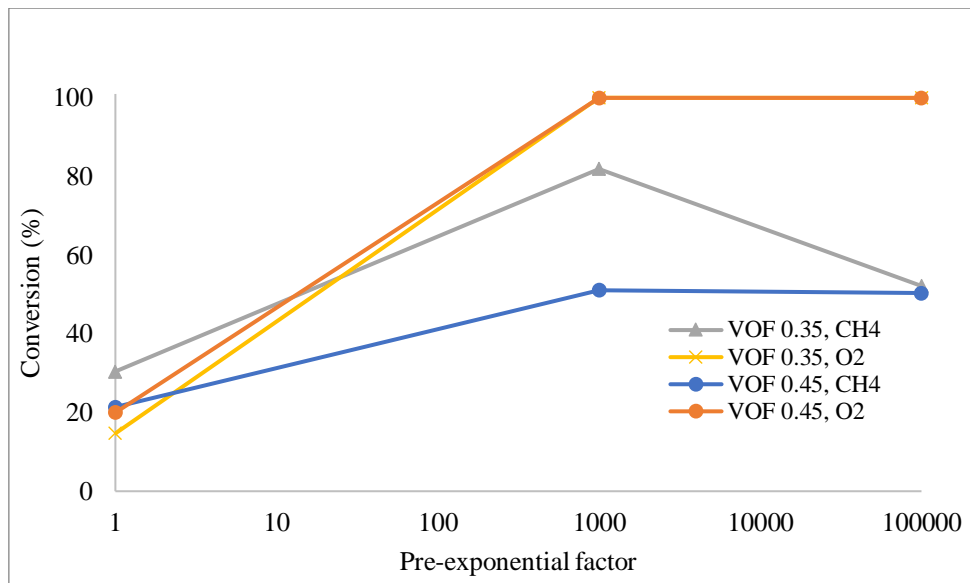

Fig. 5.16 The conversion of CH<sub>4</sub> and O<sub>2</sub> when the velocity was adjusted

Fig. 5.17 The temperature of the air reactor and fuel reactor when the velocity was adjusted

#### 5.4.4. The effect of velocity

The increase of velocity increased the homogeneity of the mixture, which increased the conversion in the reactors. In Shen's study, their result indicated that the low gas velocity led to high residence time. [119] However, too high velocity was the reason for residence time reduction, which decrease the conversion in the reactors. The velocity was adjusted from the base case at 1 and 1.5 times. For the base case, the

velocities at the risers of air and fuel reactors were 1.6 and 1.2 m/s, respectively. For the adjusted velocity case by 1.5 times, the velocity at the risers of air and fuel reactors were 2.4 and 1.8 m/s, respectively. The increase of velocity provided the decrease of CH<sub>4</sub> conversion in air and fuel reactor. On the other hand, it was not affected by O<sub>2</sub> conversion in air and fuel reactor. It indicated the air flow rate of this condition could be increased, which would increase the CH<sub>4</sub> conversion, as well. In addition, the increased velocity led to the decrease of conversion when the initial VOF was 0.35 and 0.45, as shown in Fig. 5.18. However, the increase in velocity was a significant reason for the temperature decrease, as shown in Fig. 5.19. The temperature of air and fuel were decreased when the velocity increase. The air and fuel were introduced into the reactors at 873 K, lower than the reactor temperature. The high velocity led to a high amount of mass that lower temperature, which decreased the reactor temperature.

Fig. 5.18 The temperature of air reactor and fuel reactor when velocity was adjusted

Fig. 5.19 The temperature of the air reactor and fuel reactor when velocity was adjusted

The better mixing was occurred when the initial VOF was 0.35, as shown in Fig. 5.20 and Fig. 5.21. Accordingly, the methane conversion when the initial VOF was 0.35 was higher than the methane conversion when the initial VOF was 0.45, as shown in Fig. 5.18.

Fig. 5.20 The solid volume fraction when the velocity was 1 time

Fig. 5.21 The solid volume fraction when the velocity was 1.5 times

#### 5.4.5 The effect of CH<sub>4</sub> mass fraction in the feed

The composition in feed at the riser of the fuel reactor included CH<sub>4</sub> and CO<sub>2</sub>. The CH<sub>4</sub> mass fraction of the base case was 0.3. Then the mass fraction in feed was adjusted to 0.05, 0.15, and 0.30. The high CH<sub>4</sub> mass fraction led to a low CO<sub>2</sub> mass fraction in the fuel reactor. The adjustment of CH<sub>4</sub> mass fraction would not interrupt the velocity of the fuel reactor riser. Therefore, the hydrodynamic of the fuel reactor was not affected. The decrease of CH<sub>4</sub> mass fraction from 0.3 to 0.05 would increase CH<sub>4</sub> conversion, but the O<sub>2</sub> conversion was not affected by this condition, as shown in Fig. 5.22. At the lowest of CH<sub>4</sub> mass fraction, the CH<sub>4</sub> conversion was almost complete. The fuel reactor temperature at the lowest of CH<sub>4</sub> mass fraction was the lowest, and the air reactor temperature was the highest. When the CH<sub>4</sub> conversion was high, the oxygen carrier was highly used in the CH<sub>4</sub> reaction. Therefore, the spent oxygen carrier from the fuel reactor was highly oxidized by O<sub>2</sub> in the air reactor. The temperature of the air reactor was the highest. The high CH<sub>4</sub> conversion led to a low temperature of the fuel reactor, as shown in Fig. 5.23. The reaction in the fuel reactor was endothermic. [76, 115] Accordingly, the high conversion of CH<sub>4</sub> in the fuel reactor provided the low temperature in the fuel reactor.

Fig. 5.22 The temperature of the air reactor and fuel reactor when CH<sub>4</sub> mass fraction in feed was adjusted

Fig. 5.23 The temperature of the air reactor and fuel reactor when CH<sub>4</sub> mass fraction in feed was adjusted

#### 5.4.6 The size of the reactor

The result from the hydrodynamic investigation could be further calculated the reactor size, which it was useful in the next chapter. (Economic and energy analysis) In calculating reactor size from the hydrodynamic investigation, the thermal energy was calculated from the converted CH<sub>4</sub>, as shown in Eq. 5.4. The electrical energy

was calculated from the multiplication of the thermal efficiency and the thermal energy, as shown in Eq. 5.5. The thermal efficiency was set as 55%, which was obtained from chapter 4. Finally, the reactor size was calculated from the interpolation to 50 MW electrical, which was the power production capacity of chapter 6, as shown in Eq. 5.6. The result of the reactor size was shown in Table 5.6. It indicated that the high converted CH<sub>4</sub> provided high thermal energy, high electrical energy, small reactor size, and low reactor cost.

$$\text{Thermal energy (MW thermal)} = \text{The converted CH}_4 \left( \frac{\text{mol}}{\text{s}} \right) \times \text{Heating value of CH}_4 \left( \frac{\text{MJ}}{\text{mol}} \right) \quad (5.4)$$

$$\text{Electrical energy (MW electrical)} = \frac{\text{Thermal efficiency (\%)} \times \text{Thermal energy (MW thermal)}}{100} \quad (5.5)$$

$$\text{Reactor size (m}^3\text{)} = \frac{50 \text{ (MW electrical)} \times \text{Volume of reactor from CFD simulation (m}^3\text{)}}{\text{Electrical energy (MW electrical)}} \quad (5.6)$$

**Table 5.6** The thermal energy, electrical energy, reactor size and the reactor cost

Case	Thermal energy (MW)	Electrical energy (MW)	Reactor size (m <sup>3</sup> )	Reactor cost (\$)
1	0.359	0.198	70.45	1,587,419.73
2	0.253	0.139	100.22	1,961,339.07
3	0.967	0.532	26.18	876,596.77
4	0.603	0.332	41.98	1,163,628.82
5	0.615	0.338	41.16	1,149,855.58
6	0.594	0.327	42.60	1,173,857.22
8	0.634	0.349	39.92	1,128,999.15
7	0.273	0.150	92.80	1,872,871.93
9	0.661	0.364	38.29	1,101,167.55
10	0.588	0.324	43.024	1,180,866.646

#### 5.4.7 Conclusion for the second part

The operating condition from chapter 4, pressure and Ni loading were used in this section. After that, the rate reaction, initial VOF, velocity and CH<sub>4</sub> mass fraction in feed were investigated to obtain suitable hydrodynamic behavior. This range of investigation, the high pre-exponential factor, low initial VOF, low velocity, and low CH<sub>4</sub> mass fraction in feed increased temperature and conversion. The result was validated with the experimental data. Accordingly, the operating condition from chapter 4 was reasonable. After that, the reactor size was calculated, which provided the reactor cost, as well. The cost of the reactor will be used in Chapter 6 for economic and energy analysis

## **Chapter 6**

### **The sustainability assessment of chemical looping combustion for power production**

#### **6.1 Research gaps**

In a previous CLC study, the analysis of the best case of the CLC process was investigated only thermal efficiency and economic analysis. However, the study did not investigate whether those implementations would enhance the sustainability of the improved CLC processes. The significance of thermal efficiency to the sustainability of the CLC process had not been reported. In this study, the approach for CLC process improvement from the viewpoint of sustainability analysis was reported. There were 6 case studies in which different operation conditions and configurations were investigated. The best case of 3 viewpoints (thermal efficiency, economic analysis, and sustainability analysis) was investigated. The comparison among the 3-analysis types has not been performed before. Besides, this study revealed the results, comparing combustion types between CC and CLC, the effect of the CO<sub>2</sub> capture efficiency of the CC, and the effect of thermal efficiency on sustainability analysis. The interesting point was that which approach of the operating condition or process configuration of these case studies could provide high sustainability.

#### **6.2 Objective**

To perform an energy analysis for sustainability assessment of the CLC process.

#### **6.3 Results and discussion**

##### **6.3.1 Thermal efficiency result**

The thermal efficiency indicates the efficient fuel usage for power production, as shown in Table 6.1. The high thermal efficiencies of case studies indicated that the used resources were effectively employed. Case 1, case 2, and case 3 were the power production unit from the natural gas combustion with post-combustion. The combustion section was the conventional combustion (CC). As mentioned earlier,

even though amine scrubbing was the mature process for CO<sub>2</sub> capture, the solid sorbent system was selected in this study because of its low cost and high efficiency for CO<sub>2</sub> capture. For case 1, it represents a typical power plant where there was no CO<sub>2</sub> capture section to treat the flue gas. Thus, the total produced power was the output of the plant. Consequently, the thermal efficiency of case 1 was the highest at 52.47%, and the result was comparable with the study of Kanniche et al. Their thermal efficiency of natural gas powerplant without a CO<sub>2</sub> capture system was 60%. The thermal efficiencies of case 2 and case 3 were lower than case 1, and their efficiencies were 47.48% and 50.22%, respectively. These results also coincided with Kanniche's work, which reported the thermal efficiency to be at 50% for the system with a CO<sub>2</sub> capture system. [7] In cases 2 and 3, the different CO<sub>2</sub> capture systems for post-combustion were set up. There were 6 and 3 stages for CO<sub>2</sub> capture adsorbers in case 2 and case 3, respectively. The CO<sub>2</sub> was not completely captured by the CC cases. However, the CO<sub>2</sub> was completely separated in the CLC cases. The CLC without a HAT cycle was performed in case 4. The thermal efficiency of case 4 was 39.58 %. Even though the thermal efficiency of case 4 was the lowest of all case studies, it was completely captured CO<sub>2</sub> from flue gas. Cases 5 and 6 were the CLC process with a HAT cycle, and they both had higher thermal efficiencies than case 4.

The HAT cycle improved the performance of the process by reducing the required work of the compressors and increasing the power production of the turbines. This study revealed that the HAT cycle could improve the thermal efficiency up to 13–16%, with the highest thermal efficiency (55.84%) in case 5 (Table 3). The heat exchangers in the HAT cycle for each multistage compressor reduced the workload of each compressor. At the same time, the cooling water was used in the HAT cycle to remove the heat from the compressed air and to produce steam, which was then used to increase the mass of the working fluid in the turbine. The operation of the air compressors in case 6 was different from those of other cases by employing the same compression ratio in all stages of the compressors.

On the contrary, the compression ratio of the last-stage compressor in cases 1, 2, 3, and 5 employed the highest ratio, which led to obtaining a high thermal efficiency system. The other difference in the operating conditions of case 5 and case 6 was the

amount of NiO loading. The higher loading of NiO on the Al<sub>2</sub>O<sub>3</sub> in case 6 also led to obtaining higher thermal efficiency. In addition, case 6 had lower heat recovery units when comparing to case 5. The thermal efficiency of case 6 was slightly lower than case 5. In general, from the thermal efficiency result, case 5 would be the candidate process for implementation. From the early case of the CLC study with the HAT cycle, the thermal efficiency was 56.08%, which was higher than case 5. [49] The reason for lower thermal efficiency might come from the different heat recovery processes. The thermal efficiency of the CLC process with multistage turbine 55.9% in Brandvoll and Bolland study. [120] The thermal efficiency of the CLC process with STIG was 55.1% in Ishida and Jin. [68] Eventually, the rank of these case studies from the thermal efficiency viewpoint was 5, 6, 1, 3, 2, and 4, respectively.

**Table 6.1** The thermal efficiencies for each case study.

Case	Description	Thermal efficiency (%)
1	CC and HAT without CO <sub>2</sub> capture	52.47
2	CC with HAT and 96.27% CO <sub>2</sub> capture	47.48
3	CC with HAT and 77.76% CO <sub>2</sub> capture	50.22
4	CLC without HAT	39.58
5	CLC with HAT high heat recovery	55.84
6	CLC with HAT low heat recovery	53.31

### 6.3.2 Economics analysis results

The economic analysis, which exhibited the profit of each case study, was shown in Table 6.2. Case 1 was the CC case without CO<sub>2</sub> capture. The payback period of case 1 was 6.82 y, and IRR was 13.51%. Case 2 and case 3 were operated to achieve 96.27% and 77.76% CO<sub>2</sub> removal, respectively. The payback period and IRR were 15.63 y with 4.42% for case 2 and 8.94 y with 9.86% for case 3. For case 1, the equipment and total capital costs were the lowest among all CC cases because there was no CO<sub>2</sub> capture section included. Therefore, the payback period was the shortest and the IRR was the highest. The profit of case 2 was lower than case 3 because the number of operation units in case 2 (25 units) was higher than case 3 (18 units), which were required to achieve the higher CO<sub>2</sub> capture efficiency. With this analysis, case 1

should be select for investment more than cases 2 and 3. On the other hand, this result would support the CO<sub>2</sub> emission to the environment without CO<sub>2</sub> treatment and increase the environmental loading. Accordingly, the carbon tax should be included in economic analysis for including the environmental impact.

However, if the carbon tax were included in the expenses, the payback period and IRR would be 11.44 y and 7.21% for case 1, 16.02 y, and 4.17 % for case 2 and 15.11 y and 4.77 % for case 3, respectively. It can be noted that the profit of CC cases was decreased, the payback period was extended, and IRR was decreased when the carbon tax was included. The profit of case 1 was significantly decreased because the untreated CO<sub>2</sub> from flue gas was taxed. The cost of electricity in this study was higher than in Hu's study. [121] Hu reported that the cost of electricity produced by natural gas combined cycle without CO<sub>2</sub> capture at 552.82 MW was 59.21 \$/MWh while that with post-combustion CO<sub>2</sub> capture at 467.25 MW was 87.51 \$/MWh. In this study, the cost of electricity of case 1 (CC case without CO<sub>2</sub> capture) was 94.49 \$/MWh. Those of case 2 (CC case with 96.27% CO<sub>2</sub> capture) and case 3 (CC case with 77.76% CO<sub>2</sub> capture) were 101.69 \$/MWh and 99.53 \$/MWh, respectively. The reason that the cost of the electricity in this study was higher than the cost of Hu's could be because the power plant capacity in this study was 10 times less than that in the case of Hu's.

The CLCs of natural gas were operated in cases 4–6. These cases were not taxed because it was assumed that no CO<sub>2</sub> was released to the environment when natural gas was employed in the CLC [122]. Besides, the fuel conversion was completely combusted when methane was used as a fuel. [48] However, when coal was used as fuel, CO<sub>2</sub> was found from the air reactor due to the incomplete combustion [97]. In CLC cases, the payback period and IRR were 5.73 y with 16.35 % for case 4, 6.16 y with 15.11% for case 5, and 4.60 y with 20.69 % for case 6, respectively. Case 6 showed the fastest payback period and the highest IRR among all case studies. The payback period and IRR of case 4 were slightly better than case 5 because the capital cost and operating cost of case 4 was lower than case 5, even though the thermal efficiency of case 5 was higher than case 4. Case 4 was the only case study that was not applied the HAT cycle and its thermal efficiency was low. Thus, the size of unit

operations in case 4 was increased for obtaining the same net power output at 50 MW. The IRR of case 4 was slightly higher than case 5. Case 5 had a high number of heat recovery units, which increased the heat recovery from the gas outlet of the turbine. The high number of unit operations in case 5 led to the high investment costs and low profit. Besides, the compression operation of cases 1, 2, 3, and 5 led to the large size and high investment cost of compressors. The equipment cost of other cases was higher than case 6. Thus, case 6 achieved the highest IRR and the shortest payback period among all case studies. Nevertheless, the economic analysis of CLC cases in this study was better than that previously reported for the CLC using Ni as an O<sub>2</sub> carrier in a 100 MW power production [108]. Their study concluded that the payback period and IRR of the process were 10.3 y and 16.71%, respectively [108]. The profit of cases 6 was higher because the HAT cycle was installed in this study.

From the economic perspective, case 6 was the best choice because it obtained the shortest payback period and the highest IRR, and case 1 was the second-best choice when the carbon tax was not included in the analysis. However, the inclusion of carbon tax in the plant expenses reduced the economic performance of the plant. The profit of case 1 was significantly reduced because the CO<sub>2</sub> emission, in this case, was the highest due to no installation of the carbon capture process. The installation of the CO<sub>2</sub> capture process of the CC cases was the reason for the decrease of IRR and the extension of the payback period. The CO<sub>2</sub> emission from case 2 and case 3 were 3.73% and 22.24%, respectively, while the CO<sub>2</sub> emission of CLC cases (case 4, case 5, and case 6) was almost none. Since the environmental burden should be considered in all cases, the economic analysis must include the cost of environmental damage or a carbon tax. Thus, the carbon tax would be included in both the economic and energy analyses to allow a fair comparison between processes with different CO<sub>2</sub> removal capabilities. The rank of all cases from an economic viewpoint, for both carbon tax and no carbon tax considerations, was the same at 6, 4, 5, 1, 3, and 2, respectively.

**Table 6.2** Economic analysis of all cases.

Case		Not include the carbon tax		Include carbon tax		Cost of electricity (\$/MWh)
		Payback period (y)	IRR (%)	Payback period (y)	IRR (%)	
1	CC and HAT without CO <sub>2</sub> capture	6.82	13.51	11.44	7.21	94.49
2	CC with HAT and 96.27% CO <sub>2</sub> capture	15.63	4.42	16.02	4.17	101.69
3	CC with HAT and 77.76% CO <sub>2</sub> capture	8.94	9.86	15.11	4.77	99.53
4	CLC without HAT	5.73	16.35	5.73	16.35	69.83
5	CLC with HAT high heat recovery	6.16	15.11	6.16	15.11	71.37
6	CLC with HAT low heat recovery	4.60	20.69	4.60	20.69	61.94

### 6.3.3 The emergy analysis results

All of the resources were included in the calculation. It was classified into 3 parameters; F, N and R. The 3 parameters were the local nonrenewable resource (N), the local renewable resource (R), and the external goods or the expense cost (F). The three parameters were exhibited in Table 6.3. The parameters would be calculated to be emergy indicators, unit emergy values (UEV), environmental loading ratio (ELR), emergy yield ratio (EYR), and emergy sustainability index (ESI), as shown in Table 6.4.

**Table 6.3** The F, L, and R of each case study.

Case	Process description	F (sej/Y)	R (sej/Y)	N (sej/Y)	Total
1	CC and HAT without CO <sub>2</sub> capture	6.01E+19	3.08E+19	4.21E+20	5.12E+20
2	CC with HAT and 96.27% CO <sub>2</sub> capture	6.46E+19	3.43E+19	4.65E+20	5.64E+20
3	CC with HAT and 77.76% CO <sub>2</sub> capture	6.33E+19	3.23E+19	4.40E+20	5.35E+20
4	CLC without HAT	4.40E+19	3.47E+19	5.58E+20	6.37E+20
5	CLC with HAT high heat recovery	4.52E+19	2.46E+19	3.95E+20	4.65E+20
6	CLC with HAT low heat recovery	3.91E+19	2.58E+19	4.14E+20	4.79E+20

Where F = Purchase resource, R = Local renewable resources, and N = Local nonrenewable resources

**Table 6.4** Emergy indicators of each case study.

Case	Process description	UEVs	EYR	ELR	ESI
1	CC and HAT without CO <sub>2</sub> capture	3.24E+05	8.513	15.615	0.545
2	CC with HAT and 96.27% CO <sub>2</sub> capture	3.58E+05	8.724	15.433	0.565
3	CC with HAT and 77.76% CO <sub>2</sub> capture	3.39E+05	8.454	15.569	0.543
4	CLC without HAT	4.04E+05	14.490	17.363	0.835
5	CLC with HAT high heat recovery	2.95E+05	10.280	17.933	0.573
6	CLC with HAT low heat recovery	3.04E+05	12.236	17.577	0.696

### 6.3.3.1 Case 1: CC with HAT and without CO<sub>2</sub> capture

Case 1 was the CC with a HAT cycle and without the CO<sub>2</sub> capture process. When CO<sub>2</sub> capture was not applied, the CO<sub>2</sub> capture efficiency was 0%. The investment cost, manufacturing, and service cost were the lowest of the CC case. The carbon tax of this case was the highest among the CC cases because of untreated CO<sub>2</sub>. The purchase resource, F, was the lowest of the CC cases, as shown in Table. 6.3. Even though the carbon tax was the highest, the investment and manufacturing cost of this case was lower than cases 2 and 3, as shown in Table 6.5. Natural gas was counted in nonrenewable resources, N. N of case 1 was low because of its high thermal efficiency. O<sub>2</sub> consumption in the air was also low, followed the natural gas for complete combustion. Water consumption was also low because it was not supplied to the CO<sub>2</sub> capture section. O<sub>2</sub> and water were counted as local renewable resources, R. R of case 1 was the lowest of the CC cases. The total energy flow of case 1 was the lowest among the CC cases. Accordingly, UEV of this case was the lowest of the CC cases, which indicated that it consumed low solar energy for producing 1 J of electricity, as shown in Table 6.4. However, the high F led to the low EYR and the high ELR of CC cases.

### 6.3.3.2 Cases 2 and 3: CC with HAT and a CO<sub>2</sub> capture of 96.27% (case 2) and 77.76% (case 3)

Cases 2 and 3 were the CC with HAT and CO<sub>2</sub> capture systems. CO<sub>2</sub> in the flue gas was removed at 96.27% and 77.76% for cases 2 and 3, respectively. The solid adsorber was used in the CO<sub>2</sub> capture process. The energy flows of solid metal in cases 2 and 3 was not high because it had a low cost, as shown in Tables 6.6 and 6.7. The CO<sub>2</sub> capture section of cases 2 and 3 led to high investment, manufacturing, and service costs, in which these costs were higher than case 1. Especially, the cost of case 2 was the highest of all case studies. The purchase resources, F, of cases 2 and 3, was high. The F was the highest in case 2, as shown in Table. 6.3. Natural gas was supplied to case 2 higher than case 3 because the thermal efficiency of case 2 was lower than case 3. Thus, the local nonrenewable resources, N, of case 2 was also higher than case 3 and were the highest of the CC cases, as well. O<sub>2</sub> consumption was higher in case 2 and it was higher than case 3 for complete combustion with natural

gas. Subsequently, water was also higher used in case 2 than in case 3 because the amount of flue gas in case 2 was higher than that in case 3. Since  $O_2$  and water were local resources, they were counted as R. Therefore, the R of case 2 was higher than case 3. The total energy flow of case 2 was the highest of all case studies. As shown in Table 6.4, the UEV of case 2 was also the highest among the CC cases due to the highest investment and manufacturing cost. The highest R led to the highest EYR and lowest ELR of case 2. Finally, the ESI of case 2 was the highest of all the CC cases. This result supported that power plants with  $CO_2$  capture process provided higher sustainability than those without  $CO_2$  capture process. Also, the high  $CO_2$  capture efficiency increased the sustainability of the process.

#### **6.3.3.3 Case 4 CLC without HAT cycle**

Case 4 was a CLC process without a HAT cycle.  $CO_2$  produced by natural gas combustion in the CLC process was completely captured and separated [122]. The carbon tax of the CLC was zero. The investment, manufacturing, and service costs were high, as shown in Table 6.8. In case 4, the costs of oxygen carrier and metal oxide support were the highest among the CLC cases and it was also the highest cost of solid materials in all case studies. It led to a high F even though the HAT cycle was not applied. The demand for natural gas was the highest among all case studies. Thus, N of this case was also the highest, as shown in Table 6.3. The water usage in the condensation section was the highest because of the high mass flow rate of flue gas. The process also consumed the highest  $O_2$  for the complete combustion.

Consequently, the R of this case was the highest. This case study required all resources to produce equal power capacity to other cases because it was the lowest thermal efficiency. Because of the highest required resources, the total energy flow and the UEV of this case were the highest, as shown in Table 6.4. The highest R led to the highest EYR and the highest of ESI among the CLC cases. From the sustainability aspect, this case was the best case among the CLC processes.

#### **6.3.3.4 Case 5 CLC with HAT and high heat recovery**

Case 5 was the CLC process with a HAT cycle and a high heat recovery system. The investment, manufacturing, and service costs were the highest of all CLC

cases because of the high number of unit operations, leading to the highest F of all CLC cases, as shown in Table 6.3. This case utilized the lowest oxygen carrier and metal oxide support because less natural gas was consumed since the process had high thermal efficiency. Therefore, N of this case was the lowest. O<sub>2</sub> in air consumed in the process was also the lowest among all case studies, as shown in Table 6.9.

Consequently, the R of this case was the lowest. The total energy flow was the lowest; thereby, the UEV was the lowest, as shown in Table 6.4. It indicated that this case used the lowest solar energy for producing electricity. However, the highest F and the lowest R of this CLC case led to the lowest EYR and the highest ELR of the CLC cases, representing the low sustainability of the process and high environmental loading. Consequently, the ESI of this case was the lowest of the CLC cases.

#### **6.3.3.5 Case 6 CLC with HAT and low heat recovery**

Case 6 was the CLC process with a HAT cycle and a low heat recovery system. The oxygen carrier was slightly higher than case 5, but the metal oxide supporter was extremely lower than case 5 because the Ni loading of case 6 was higher than case 5, as shown in Tables 6.9 and 6.10. The investment, manufacturing, and service costs were the lowest of all case studies because of the different compression operation methods. Accordingly, F of case 6 was the lowest of all case studies, as shown in Table 6.3. The natural gas consumption was slightly higher than case 5 because of its lower thermal efficiency. N of this case was higher than case 5 but was lower than case 4. More O<sub>2</sub> in the air was consumed to complete the combustion with natural gas. Therefore, O<sub>2</sub> in air and R of this case would be higher than case 5 but lower than case 4. The low investment, manufacturing, and service costs led to lower total energy flow. The UEV of this case was low and was slightly higher than case 5, because of the lower purchased resources, as shown in Table 6.4.

#### **6.3.3.6 The conclusion on energy analysis**

The UEVs of all six case studies were higher than those previously reported for a geothermal power plant, 2.18E+05 (sej/J), coal power plant, 1.63E+05 (sej/J), wind power plant, 1.74E+04 (sej/J), and hydropower plant, 5.04E+04 (sej/J) [123]. For the CC cases, the UEV of case 1 (3.24E+05 sej/J) was the lowest even though the

carbon tax was included. The UEV of case 2 ( $3.58\text{E}+05$  sej/J) was slightly higher than case 3 ( $3.39\text{E}+05$  sej/J), which reflects the higher solid sorbent, support, investment, and operating costs of case 2, but the carbon tax of case 3 ( $3.40\text{E}+18$  sej/y) was some 5.5 times higher than case 2. Eventually, the total energy of case 2 was still higher than case 3 for producing the same amount of electricity. For the CLC cases, the UEV of case 5 was the best because the thermal efficiency of case 5 ( $2.95\text{E}+05$  sej/J) was the highest. The UEV of the CLC was lower than CC cases because the carbon tax effect was included in the CC cases, except case 4 ( $4.04\text{E}+05$  sej/J). The UEV of case 4 was higher than CC cases because the demand for natural gas of case 4 was the highest among all case studies. The UEV of case 6 ( $3.04\text{E}+05$  sej/J) was slightly higher than case 5 because the demand for natural gas of case 6 was higher than case 5.

For EYR, ELR and ESI comparison, N, F, and R of CC cases were higher than CLC cases. The low value of F in CLC cases was the reason for obtaining high EYR, which indicated the high stability of the process. Accordingly, the stability of CLC cases was higher than in CC cases. The energy flow of oxygen carrier (NiO) in CLC cases was higher than solid sorbent ( $\text{Na}_2\text{CO}_3$ ). The energy flow of solid was included in F. Therefore, the %F was high and %R was low in CLC cases. The high value of %R in CC cases was the reason for obtaining low ELR, which indicated the low loading to the environment. The analysis showed that the environmental loading in the case of CLC cases was higher than those of CC cases. Eventually, the sustainability of the process has to consider both the process yield and the environmental loading and the ESI is an indicator which is the ratio between EYR and ELR. It was found that the ESI of the CLC cases were higher than those of CC cases. It shows that the CLC cases were more sustainable than the CC cases. The rank of the ESI of all case studies was 4, 6, 5, 2, 1, and 3, respectively.

Fig. 6.1 The sensitivity of natural gas to EYR, ELR, ESI and UEV.

### 6.3.3.7 The sensitivity of emergy analysis.

The high value of ESI could be obtained by decreasing the ELR or increasing the EYR. From Tables 6.5 to 6.10 the emergy of natural gas was the largest fraction of the total emergy in all cases. Subsequently, the variation of natural gas emergy would highly affect the sustainability assessment of these processes. Natural gas was the only component of  $N$ . The increase of natural gas would reduce the ESI since it increased the ELR higher than the EYR. The UEV was another significant parameter of the emergy analysis that was used for comparing process performance. The UEVs in Fig. 12 were calculated from the total emergy flow divided by the emergy of power

production. The increase of natural gas's energy would increase total energy, which was the cause of increasing UEV of power production. On the other hand, the decrease in natural gas energy would decrease the UEV. The 20% variation of natural gas energy gave the UEV in the range of  $2.51E+05$  and  $4.75E+05$  sej/J, which was close to the UEV of power production in other studies ( $8.05E+04$  sej/J) [125]. Subsequently, ESI for each case study was in the range of 0.55 and 0.84. The 20% variation of natural gas energy value did not change the rank of sustainability of all the case studies when compared with the base case. This sensitivity confirmed that the result from the energy analysis was reliable comparing to other studies [123, 126-128].

From the result of the reactor cost calculation in chapter 5, the cost of the reactor which calculated from the hydrodynamics investigation was increased from \$  $1.0E+5 - 4.2E+5$  to be \$  $8.7E+5 - 2.0E+6$  with different considered reactors. However, the equipment cost and the manufacturing cost was accounted for only 10% of the total energy. The reactor cost calculated based on data from chapter 5 was not highly affected the sustainability of the process. Besides, the increased equipment cost affected the F fraction. The trend from the increase in equipment cost would give the result similar to the sensitivity investigation.

#### **6.3.3.8 Another scenario: natural gas as an imported resource**

This investigation is to explore the significance of domestic or foreign resources on system sustainability. In the previous section, natural gas was considered a nonrenewable local resource. Thus, its contribution was included in the N. However, in this section, natural gas was considered as an imported resource. Therefore, its contribution would be included in the F. When natural gas was an imported resource, it does not change the values of UEV and ELR. However, it led to the decreased EYR because the numerator decreased. The results of the analysis are summarized in Tables 6.11 and 6.12. The sustainability of the process, ESI, decreased when resources of the process highly depended on the external resources. It was also noted that the EYR decreased drastically and the ESI of CC cases was slightly higher than CLC cases, which contradicted the former scenario. The ESIs of all cases were much lower than those of domestic natural gas cases. However, the CC case with the CO<sub>2</sub>

capture process, case 2, provided slightly better ESI than the other cases. Comparing these two scenarios, the ESI of the former scenario was much higher than the latter. That is, if natural gas were a domestic resource, the system would be more self-sufficient. The analysis also shows not only process technology but also the sources of the major raw materials that determine the sustainability of power production.

**Table 6.11** The F, L, R and N fractions of each case study when natural gas was included in the F fraction.

Case	Process description	F (sej/Y)	R (sej/Y)	N (sej/Y)
1	CC and HAT without CO <sub>2</sub> capture	4.81E+20	3.08E+19	0

#### 6.4 The three analysis tools comparison

From the evaluation, it was found that the best case was depended on the types of analysis. In this study, three types of analysis for decision making were considered based on thermal efficiency, economic performance, and emergy evaluation. The thermal efficiency indicated the effectiveness of fuel usage. Case 5 was the best solution since it gave the highest efficiency (55.84%). The ranking of thermal efficiency was 5, 6, 1, 3, 2, 4. This analysis should not be selected because the process without CO<sub>2</sub> management (case 1) would be selected before the process CO<sub>2</sub> management (case 2, 3 and 4). The economic analysis indicated the profit for investment. Case 6 was best solution which it had 20.69 % IRR and 4.60 y of the payback period. When the environmental impact was included in economic analysis by include carbon tax, the ranking of economic performance was not changed. However, the emergy analysis also gave a different conclusion from the former analyses. The emergy analysis showed that case 4 was the best case because it had the highest ESI (0.835). The high ESI indicated the high sustainability. In emergy analysis, UEV indicated the usage of global resource, EYR indicated the economic

performance, ELR indicated the environmental loading, and ESI indicated the sustainability. Accordingly, the perspective of thermal efficiency and economic analysis were included in the energy analysis. Case 5 was the best case in only the effectiveness of resources usage but low economic performance. Case 6 was the best case in economic performance, but the sustainability of case 6 was lower than case 4. Even though, the thermal efficiency of case 6 was low, but it was the highest sustainability. Accordingly, the resource usage, the economic performance and the environmental impact of case 4 was the best in the long period which could be operated with stability.

## 6.5 Conclusion

The main objective of this study was to evaluate technologies and their operations for decision making on power production. The effects of combustion types (CC and CLC), the CO<sub>2</sub> capture efficiency, and the process configuration and operation were investigated. Since the energy index is a holistic parameter that takes many factors into account, which were resource management, economics, environment, and sustainability, ESI. Accordingly, energy analysis could be the better decision-making indicator. From the above analysis, case 4 could be the solution to this power production since it had high sustainability index and relatively high economic performance. The result also indicated that thermal efficiency alone was not adequate for the conclusion of technology selection since it considered only the efficient use of energy while ignoring other operating factors. The economic analysis had included all costs of the built plant, but it did not consider the environmental burden. Thus, the carbon tax or environmental tax could improve the economic model to satisfy both economic and environmental issues. However, some natural resources or environmental capitals were also not included in the current economic model. On the contrary, the energy analysis was the tool that incorporates various factors from several dimensions, such as natural resources, human workforce, economics, environment, and others, into the analysis so that the evaluation could give a better holistic view of the solution than the former analyses.

## Chapter 7

### Conclusion and suggestion

#### Conclusion of the study

This study investigated the chemical looping combustion (CLC) process improvement for power production from energy management, system hydrodynamics, and a sustainability perspective.

In the first part, energy management was investigated to achieve the highest thermal efficiency of the CLC process with the HAT cycle for power production. The limitation of previous studies of the CLC study has individually investigated the effect of each parameter. However, the synergistic of the parameters in the system may influence each other. In this study, the  $3^k$  factorial design was used for exploring these parametric effects and indicating their interaction with the systematic treatment. The power production from the air reactor is 2-5 times higher than the power production from the fuel reactor. Therefore, the parameters that might affect the power production from AR were selected, which including of 1) pressure of air reactor, 2) the number of air compressors, 3) compression ratio and 4) air flow rate. All of the case studies were simulated by Aspen plus program. The result indicated the pressure of the air reactor and compression method highly affected the thermal efficiency. The high pressure and method 3 provided high thermal efficiency. Method 3 provided high thermal efficiency because it led to the highest temperature discharged from the compression, which contributed to high power production from the air reactor and high thermal efficiency. With the systematic investigation, the thermal efficiency of the CLC process with the HAT cycle had higher than the previous study (57.7%). The optimum operating condition from this section would be used in the second and last parts.

In the second part, CLC could be used with solid and gaseous fuels. The challenge of solid fuel operation is incomplete combustion because of the slow gasification rate. The challenge of gaseous fuel operation is the improper operating condition, which provides the CO<sub>2</sub> emission to the environment. Accordingly, the operating conditions are crucial for suitable hydrodynamics achievement and the CO<sub>2</sub> capture efficiency of the system. The dual circulating fluidized bed reactor (DCFBR) was selected for the CLC system and investigated its operation by

2-D computational fluid dynamics (CFD) simulation. The CFD simulation was conducted by solving three conservative equations; continuity, momentum and energy of the considered system. The Eulerian method and the kinetic theory of granular flow were also used in this study. In this section, there were 2 objectives. First, it is to specify the suitable hydrodynamics' operating condition in the full-loop DCFBR for the CLC process. Second, hydrodynamic investigation of operating condition which achieved high thermal efficiency. The result for the solid fuel, the system hydrodynamics had validated with the experimental data before the model was further used in the study. The result of the operating conditions indicated that the low temperature and the low ratio of coal velocity to the oxygen carrier's weight provided the best performance of this system. For the gaseous fuel, the obtained operating conditions from the former investigation were used in this part. The result indicated high pre-exponential factor, low initial solid volume fraction (VOF), low velocity, and low CH<sub>4</sub> mass fraction in feed increased temperature and conversion. After that, the reactor size was estimated to provide the reactor cost. It will be used for economic and energy analyses. Suitable hydrodynamic behavior provides good mixing and correct flow direction. From the simulation, it suggested keeping low velocity and low solid in the reactor. For the actual operation, the pressure balance at the loop seal was a crucial point to operate to obtain good hydrodynamic behavior, which provides the high performance of the CLC reactor.

In previous CLC study, the improvement of CLC had been developed only the efficiency and economic analysis viewpoints. However, the CLC process in sustainability improvement had not been investigated. In the last part of the study, three analyses, which were energy performance, economics, and sustainability, were evaluated to identify the best case of the CLC process by aiming to enhance the process sustainability. The energy analysis investigated the sustainability of the process. Besides, six case studies were investigated to identify the effects of the combustion types (conventional combustion (CC) and CLC) and the system configuration (CO<sub>2</sub> capture stages and operating conditions). The case studies included 1) CC without CO<sub>2</sub> capture, 2) CC with HAT at 96.22% CO<sub>2</sub> capture, 3) CC with HAT at 77.76% CO<sub>2</sub> capture, 4) CLC without HAT, 5) CLC with HAT with high heat recovery, and 6) CLC with HAT with low heat recovery. The result indicated the

best-case study depending on the analysis, which obtained a different viewpoint. However, the emergy analysis expressed the holistic perspective, including the resource, the competition of investment, environmental loading, and sustainability. The sustainability of CLC was higher than in CC cases. The configuration and operating conditions affected the sustainability of the process. Case 4 was the best-case study because it obtained the highest sustainability since its local resource fraction was the highest. It reflected the self-sufficiency of this case was higher than others. The result indicated that the further improvement of the CLC process to achieve high sustainability was the increase of local resource dependence, especially the renewable local resource. On the other hand, when considering the process from the global viewpoint, case 5 will be the best since its UEV was the lowest. It implies the least natural resource consumption of the considered process.

#### **Suggestion for the further study**

The improvement of the CLC process in the perspective of sustainability was a novel investigation. From the emergy analysis, there are various potential factors to improve the CLC process's sustainability. First, by increasing the local renewable resources, the sustainability of process will be increased. O<sub>2</sub> in air and water are counted as the local renewable resources. The uses of O<sub>2</sub> in air and water in the system should be systematically investigated against the optimal sustainability index. The fuel for the fuel reactor could be changed to local renewable fuel, such as biomasses. Second, the type and life of an oxygen carrier should be considered since the oxygen carrier's transformity was high. Therefore, oxygen carrier materials with the same performance, but lower transformity should be investigated. The life expectancy of the oxygen carrier should also be considered since it will reduce its annual consumption. However, the materials' reactivity will also affect reactor hydrodynamics. Changing the oxygen carrier could need the reactor hydrodynamic investigation.

## Index

The information for hydrodynamic investigation in chapter 5.

The heat capacity of all species in the mixtures was provided for consistent with Eq. I.1, as shown in Fig. I.1. The input data was shown in Table I.1. The heat of formation of mixtures was shown in Table I.2.

$$C_P = C_1 + C_2T + C_3T^2 + C_4T^3 + C_5T^4 + C_6T^5 \quad (\text{I.1})$$

Range	Minimum	Maximum	Coefficients
1	50	1500	6

**VITA**

<b>NAME</b>	Watchara Uraisakul
<b>DATE OF BIRTH</b>	9 December 1987
<b>PLACE OF BIRTH</b>	Lampang
<b>INSTITUTIONS ATTENDED</b>	B.Sc and M.Sc Chemical Engineering, Chulalongkorn University
<b>HOME ADDRESS</b>	109/145, Moo 3, Tumbon Klongsuanploo, Ayutthaya 13000
<b>PUBLICATION</b>	<ol style="list-style-type: none"><li>1) CFD simulation of fuel reactor in chemical looping combustion</li><li>2) Hydrodynamics of dual circulating fluidized bed reactor for chemical looping combustion</li><li>3) Sustainability of natural gas chemical looping combustion from efficiency, economic and energy analyses</li></ol>
<b>AWARD RECEIVED</b>	-
