KEYWORD:

Ngoc Thanh Nguyen : GROUNDWATER POTENTIAL MODEL USING STATISTICS AND HYBRID MACHINE LEARNING APPROACHES. Advisor: Prof. SRILERT CHOTPANTARAT, Ph.D.

The present study was conducted to delineate the groundwater potential in Kanchanaburi Province, Thailand based on groundwater yield, groundwater contamination risk, and groundwater quality. In this study, an ensemble model was created by combining Analytical Hierarchy Process, Frequency Ratio, and Random Forest to evaluate the spatial distribution map of the groundwater resources. Additionally, a new hybrid approach was developed based on maximum entropy and analytical hierarchy process to delineate the Ni contamination risk in groundwater. Finally, four machine-learning models, including Random Forest - Cross validation, Random Forest - Bootstrap, Artificial Neural Network - Cross validation, and Artificial Neural Network - Bootstrap were used to decipher groundwater quality. The results indicated that the ensemble model was better than individual models in delineating groundwater yield potential. Poor and moderate potential with groundwater yield $> 10 \text{ m}^3/\text{h}$ was distributed mainly in the western Kanchanaburi, while the eastern regions showed high groundwater yield potential (bao nhiêu m^3/h). In terms of contamination risk, the hybrid model between maximum entropy and analytical hierarchy process gave a high performance with an Area Under Curve of 0.86 and Accuracy of 0.85. The map of Ni contamination risk in groundwater showed that approximately 24.79% of the eastern Kanchanaburi (1691.82 km^2) was a very low contamination risk of Ni.

ACKNOWLEDGEMENTS

I deeply express my gratitude and appreciation to my thesis advisor Prof. Dr. Srilert Chotpantarat for his support and guidance throughout the entire process of this research.

I would like to express my sincere thanks to all lecturers and staffs at Interdisciplinary Program in Environmental Science, Graduate School, Chulalongkorn University for their continuous support and useful comments. I am especially thankful to the Graduate Scholarship Program for ASEAN countries and the 90th Year Chulalongkorn University Scholarship, Chulalongkorn University for the financial support throughout the study period of my Ph.D. program. In addition, I would like to express my heartfelt appreciation to the Thailand Department of Groundwater Resources for providing databases for my research.

I would also like to thank the Department of Environmental Science and the Department of Geology, Faculty of Science, Chulalongkorn University for kindly allowing me to use the facilities. I would like to thank the members of Prof. Dr. Srilert Chotpantarat's Lab for their kind help during the field trips. I am grateful to Assoc. Prof. Dr. Nguyen Huu Ngu, Hue University of Agriculture and Forest for kindly advising me to develop this thesis book. I also would like to thank Dr. Nguyen Huu Trung, Queensland University of Technology, for advising me during the data analysis. Special thanks are given to the Committee members of my doctoral dissertation for the thorough reviews to have this success.

One of the most important things to reach success in my study that I have never forgotten is the great support in terms of spiritual and material from every member of my great family and friends. I endlessly thank my parents and wife for being always beside and encouraging me during my study. The best Vietnamese and Thai friends have been encouraging and sharing cheerful smiles for me to overcome the challenges of studying far away from home.

Chapter 1. INTRODUCTION

1.1. Statement of the problem

Water is vital for the existence of all life on the Earth and an essential component of several manufacturing operations in a nation. In recent decades, freshwater shortages in many regions have demanded research on the sustainable use of water resources (Chen et al., 2020; Hou et al., 2020; Zehtabiyani-Rezaie et al., 2019), based on the effects of weather elements and human activities on these resources. The intricate process of climate change has caused widespread drought, changes in location, timing form, the number of precipitations, and tropical storm intensity in many areas of the world (Dai, 2013). Rising sea levels have led to salinity intrusion in soil and groundwater in desert and coastal regions (Boonkaewwan et al., 2020; Howard et al., 2010; Shah et al., 2001). Simultaneously, population growth, agricultural expansion, urbanization, and modern industrial activities have created an increasingly large need for freshwater (Francis, 2011; Howard et al., 2010; McDonald et al., 2011; Wilson et al., 2006). To reduce freshwater shortages, the exploitation and sustainable use of water resources have garnered increasing attention, particularly with regard to groundwater. The development of groundwater potential maps is becoming increasingly important in many scientific fields and nations (Chaminé et al., 2015). In particular, groundwater mapping provides suitable locations for drilling groundwater wells for the purpose of water resource management and agricultural activities (Ahmed and Sajjad, 2018; Elbeih, 2015). Simultaneously, a groundwater potential map can reveal the groundwater potential zone of a given region. Additionally, human development and changes in natural processes lead to negative aspects of groundwater quality (Li et al., 2017; Shah, 2005; White et al., 2007). The presence of heavy metals causes considerable concern in various water uses. Consequently, assessing the concentration of toxic pollutants in groundwater is urgently needed in many regions and countries worldwide.

Constantly advancing remote sensing (RS) and geographic information system (GIS) technology has played a vital role in groundwater hydrology in recent decades. GIS is an appropriate tool for solving spatial attribute problems in many environmental science fields (Beck, 2003; Chaudhary and Kumar, 2018; Chowdhury et al., 2009; Edet et al., 1998; Twumasi and Merem, 2006), particularly hydrology and hydrogeology. The information RS provides for the Earth's surface facilitates groundwater potential research in many regions that do not have available data and complex topography. In recent years, several groundwater studies have utilized RS and GIS technology to map groundwater potential zones in their areas of interest. Some scientists (Ghosh et al., 2016; Gnanachandrasamy et al., 2018; Kallali et al., 2007; Machiwal et al., 2011; Pinto et al., 2017; Selvam et al., 2016) have used statistical models such as multi-criteria decision analysis (MCDA), multi-influence factor (MIF), analytical hierarchy process (AHP), frequency ratio (FR) model, logistic regression (LR) model, and evidence belief function (EBF). Other researchers have applied machine learning approaches to analyze, calculate, and map the groundwater potential zone (Alizamir et al., 2018; Kamali Maskooni et al., 2020; Lee et al., 2019; Sahoo et al., 2017; Tan et al., 2020). Machine learning models are often used in groundwater studies, including AB-AD Tree, quadratic discriminant analysis, K-neighbor classification, random forest classifier (RFC), and support vector machine (SVM). The purpose of these models is to delineate areas with large groundwater reserves to exploit and reasonably use groundwater. Although some attempts have been made to develop these models for assessing the groundwater potential for a given region, the accuracy of the models has reportedly ranged from 50% to 92% (Abijith et al., 2020; Kamali Maskooni et al., 2020; Pham et al., 2019; Tien Bui et al., 2019) with regard to the establishment of potential groundwater maps. The improvement of groundwater potential mapping models has a significant role in determining the successful location of groundwater wells. This not only helps establish wells but also guides the sustainable use of groundwater resources.

In this study, Kanchanaburi Province in Thailand is considered because its

groundwater situation faces many problems such as drought and contamination (Srirattana et al., 2021). Moreover, groundwater extraction increases rapidly to meet the demand for domestic and agricultural irrigation (Putthividhya and Pipitsombat, 2018). However, the groundwater potential map in terms of quantity and quality in this province is still limited. Hence, it is necessary to assess groundwater potential for various purposes in Kanchanaburi Province, Thailand. The anticipated output of this study will contribute new approaches in groundwater potential study not only for the study area but also for other regions in the world.

1.2. Research Objective

The general objective of the research is to delineate the groundwater potential zones in terms of quantity and quality in the Kanchanaburi Province, Thailand, where groundwater has been widely used by the inhabitant for their various needs.

1.3. Specific objectives

a) to develop a new ensemble model to efficiently evaluate the spatial distribution map of the groundwater resources.

b) to develop a new hybrid model to delineate the heavy metal contamination risk zone in groundwater.

c) to delineate groundwater quality using the Entropy water quality indexes.

1.4. Research questions

1. How is the spatial distribution of groundwater yield in the study area?
2. Which database and models are suitable for the study area?
3. How is the level of heavy metals contamination risk in groundwater in the study area?

4. Is the hybrid model acceptable for heavy metal risk assessment in groundwater?

5. Which model is acceptable for deciphering groundwater quality?

6. What is the suitability of groundwater potential for different uses?

1.5. Hypothesis

1. The new hybrid approaches (AHP, FR, RF) can effectively assess groundwater potential in a case study of Kanchanaburi Province, Thailand.

2. The new hybrid approaches (Maxent and AHP) can effectively delineate the heavy metal contamination risk zone in groundwater in a case study of Kanchanaburi province, Thailand.

3. The machine learning models can effectively decipher groundwater quality in a case study of Kanchanaburi Province, Thailand.

1.6. Expected outcome

1. A map of spatial distribution of groundwater yield in Kanchanaburi, Thailand using frequency ratio, random forest, and analytic hierarchy process.

2. A map of contamination risk zones in groundwater in Kanchanaburi, Thailand.

3. A map of groundwater quality in Kanchanaburi, Thailand.

Chapter 2. THEORETICAL BACKGROUND AND LITERATURE REVIEWS

2.1. Definition of groundwater potential map

Previous literature reviews indicate that the definition of GWP is a general concept depending on the purpose of each research. Some researchers ([Andermann et al., 2012](#); [Fischer et al., 2003](#); [Rodell et al., 2007](#); [Yeh et al., 2006](#)) have focused on groundwater storage, while others ([Batte et al., 2008](#); [Janakarajan and Moench, 2006](#); [Nampak et al., 2014](#)) have analyzed the groundwater yield in an area. From a storage perspective, GWP is defined as the total amount of water in aquifers that can be stored for a long time ([Kebede, 2013](#)). Considering the yield, GWP is the quantity of groundwater that may be extracted from a groundwater aquifer without surpassing the long-term recharge or the chemical and physical integrity of the basin ([Greer, 2008](#)). In addition to the above aspects, groundwater quality is also used to delineate GWP zones for different purposes. [Hounsinou \(2020\)](#) considered the extent of saline intrusion of seawater to set the GWP boundaries. [Dhar et al. \(2015\)](#) defined the GWP zones by overlaying the GWP and groundwater quality indexes. Consequently, the definition of GWP is not a specific concept to use uniformly worldwide. The usage of groundwater storage or yield to define GWP remains controversial because they ignore factors, such as groundwater quality, aquifer properties, sensitivity, contamination, and its intended use. The definition of GWP based on the knowledge of the authors can be stated as follows: “Groundwater potential is the volume of groundwater that can be withdrawn from an aquifer for a particular purpose without affecting the groundwater yield and groundwater quality of an aquifer.”

2.2. Number of publications in groundwater potential field

The study area statistics around the world provide hydrologists with a general picture of GWP research. It shows the level of interest in groundwater reserves in different parts of the world. It is the basis for international organizations to select and

implement projects related to the conservation of global groundwater resources. In this section, information regarding the number of research papers on GWP and other parameters is presented. The content includes information about the number of national studies. The information given in Fig. 2.1 was collected from two reliable sources, namely Scopus and Web of Science, with keywords “groundwater potential + year,” applied by the “title, abstract, and keywords” search functions. A total of 872 and 707 articles were found in Scopus and Web of Science in this field from 2010 to 2020, respectively. Overall, the number of articles related to GWP map research has remarkably increased in this period (Fig. 2.1), with 87 countries of interest according to authors (Fig. 2.2). Fig. 2.2 also shows the level of interest by hydrologists regarding GWP worldwide over the past decade. India, Iran, and Nigeria had a high number of publications in this research field. Only a small number of relevant studies have been conducted in the rest of the countries (Fig. 2.2). Fig. 2.3 shows the top 10 journals of Scopus and Web of Science systems selected by authors for publication between 2010 and 2020, in which Environmental Earth Sciences and Arabian Journal of Geosciences had the highest publication.

Fig. 2.1. Number of GWP studies in the world between 2010 and 2020

Fig. 2.2. Map of the nations with studies in the world groundwater potential map published from 2010 to 2020 in the Scopus (a) and Web of Science (b) database

Fig 2.3. Top 10 journals considering number of publications on GWP in the Scopus (a) and Web of Science (b) database from 2010 to 2020

2.3. Parameters, model techniques and validation in groundwater potential studies

The dataset related to this study is compiled from two sources, namely Scopus and Web of Science, and conducted as shown in Fig. 2.4. The first step involves searching the literature. A total of 872 publications on Scopus and 707 publications on Web of Science are related to GWP. The second step is cross-referencing literature between the two systems using DOI and the title of papers. A total of 1085 publications were found in the GWP field from 2010 to 2020. The third step is the calculation of the number of representative samples using Slovin's formula (Marendra and Tangahu, 2020) (Eq. 1).

$$n = \frac{N}{1 + Ne^2} \quad (1)$$

where N is the total of 1085 publications, e is the error margin (0.1), and n is the number of representative samples. The fourth step is setting the dataset. A total of 91 publications are selected for this study based on the citation index from high to low (Table 2.1). The final step is reviewing the content on parameters, models, and validation techniques. This step is the most time-consuming procedure in the research process.

Abbreviations of input parameters: DS - Slope (degree/percentage); AS - Slope aspect; AL - Altitude/Elevation; TWI - Topographic wetness index; LS - Slope length; C - Curvature; PIC - Plan curvature; PC - Profile curvature; RD - River density; DWF - Distance to water bodies/rivers; DIF - Distance to faults; L - Geology/Lithology; LU - Land use; DD - Drainage density; LD - Linearment density/Fault density; F - Fault/lineament; D - Drainage; DID - Distance to drainage; R - Rainfall/Precipitation; S - Soil; SD - Soil depth; SPI - Stream power index; STI - Sediment transport index; NDMI - Normalized difference vegetation index; Ge - Geomorphology; GWD - Groundwater depth; NR - Net recharge; WTL - Water table level; ATH - Aquifer thickness; AR - Aquifer resistivity; RP - Relative permeability map; AT - Aquifer type; DHR - Distance to roads; GWO - Groundwater quality; CI - Convergence index; RSP - Relative slope position; TRI - Terrain ruggedness index; TPI - Topographic position index; ST - Surface temperature; RC - Runoff coefficient; RL - Relief; FD - Flow direction. **Abbreviations of models:** AB - AdaBoost; AIP - Analytic hierarchy process; ANFS - Adaptive neuro-fuzzy inference system; ANN - Artificial neural network; ANP - Analytical network process; BA - Bees algorithm; BBO - Biogeography-based optimization; BG - Bagging; BTR - Boosted regression tree; CART - Classification and regression tree; CF - Certainty factor; CG - Cascade generalization; DE - Differential evolution; DLR - Dagging; DS - Decision Stump; DT - Decision Tree; EBF - Evidential belief function; EBFTM - Evidential belief function and tree-based; FA - Firefly algorithm; FDA - Flexible discriminant analysis; FLDF - Fisher's linear discriminant function; FR - Frequency ratio; FREM - Frequency ratio data mining ensemble model; GAM - Generalized additive model; GLM - General linear model; GRF - Genetic algorithm optimized random forest; IWO - Invasive weed optimization; KNN - K-nearest neighbor; LDA - Linear discriminant analysis; LR - Logistic regression; MARS - Multivariate adaptive regression spline; MB - MultiBoost; MCDM - Multi-criteria decision making; MIF - Multi influencing factor; MX - Maximum entropy; NB - Naive Bayes; PDA - Penalized discriminant analysis; PSO - Particle swarm optimization; ODA - Quadratic discriminant analysis; RF - Random forest; RS - Random subspace; RSE - Random subspace Ensemble; RTF - Rotation forest; SI - Statistical Index; SRF - Self-learning random forest; SVM - Support vector machine; SVML - SVM - linear; SVMP - SVM - polynomial; SVMR - SVM - radial; SVM5 - SVM - sigmoid; TLBO - Teaching learning based optimization; WQEI - Weights of evidence.

2.3.1. Input parameters in groundwater potential studies

GWP studies are generally developed on the basis of climate, geology, hydrology, land cover, topography, and aquifer-related data. A total of 41 input parameters are related to the identification of groundwater-rich areas (Fig. 2.5). The number of input parameters necessary to establish the GWP map is different in each study. This number ranges from 2 to 17 parameters. Input parameters are the required information of a GWP model. These parameters provide databases related to GWP and are the basis for model application. The frequency of input parameters used in GWP studies is depicted in Fig. 2.5. These data are usually extracted from conventional data, existing maps, remote sensing, and survey. Eight common factors, including geology, slope, land use, soil type, drainage density (DD), fault/lineament density, altitude, and rainfall with a usage frequency larger than 50%, are available in GWP studies during 2010–2020.

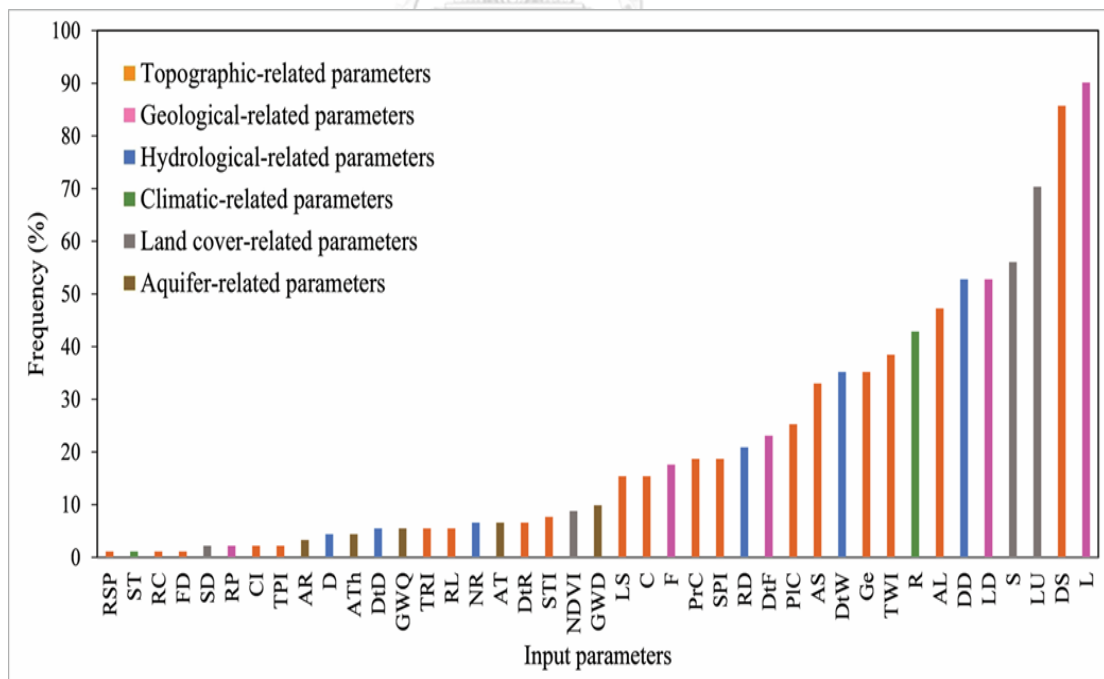

Fig. 2.5. Frequency of factors used in GWP studies from 2010 to 2020

2.3.1.1. Topographic-related parameters

Topographic-related parameters are factors that describe the topographical features of a study area. The frequently used topographic parameters in GWP research include the following: slope, slope aspect, altitude, topographic wetness index (TWI), slope length, curvature, plan curvature, profile curvature, stream power index, sediment transport index, geomorphology, distance to roads, convergence index, relative slope position, terrain ruggedness index, flow direction, and relief. Furthermore, five topographic-related parameters, namely slope, slope aspect, altitude, TWI, and slope length, were widely utilized in most GWP studies (Fig. 2.5). Slope controls the percolation of water into the soil (Ali et al., 2015). Magesh et al. (2012) proved that a gentle slope means that surface water has less residence time on the ground. This leads to water having more time to seep into the ground, whereas a high slope increases flow speed and erosion, and therefore, rainwater does not have sufficient time to infiltrate. Areas with low slopes have negative surface runoff and positive percolation rates, whereas areas with high slopes usually have high amounts of soil runoff and fast meteoric water evacuation by direct hitting water/or rainfall. Adiat et al. (2012) concluded that groundwater recharge depends on the surface flow velocity and vertical percolation controlled by slope degree. Naghibi and Pourghasemi (2015) indicated that the slope aspect also affects hydrological processes because it determines rainfall direction, moisture, plant growth, and snow melting. Tahmasebipoor et al. (2016) determined that groundwater is often limited at high altitudes and abundant at low elevations. Rahmati et al. (2016) applied TWI to measure the amount of runoff accumulation at any place in a basin. GWP partly explains a strong inverse correlation between the TWI index and groundwater yield. Naghibi et al. (2017a) indicated that the possibility of soil loss also impacts GWP, which is calculated on the basis of slope length. GWP is also high when the slope length value is low. Overall, topographic-related parameters control permeability, surface flow direction, and number of precipitations

seeping into the soil. In the last decade, the growth of the aerospace industry has greatly contributed to many scientific fields. Digital elevation models (DEMs) are useful for determining the topography of a certain area (Agarwal and Garg, 2016; Pradhan et al., 2020; Rajasekhar et al., 2019). DEM is usually taken from the Shuttle Radar Topography Mission (SRTM) (Arkoprovo et al., 2012; Nanda et al., 2017; Prasad et al., 2020) or ASTER sensors (Mosavi et al., 2020; Sachdeva and Kumar, 2020; Waikar and Nilawar, 2014) and stored in a raster format. Topographic data are normally extracted from digital elevation information.

2.3.1.2. Geological-related parameters

Geological-related parameters are commonly accepted to govern the potential of groundwater. In GWP mapping studies, distance to faults, geology, lineaments, lineament density, and relative permeability factors are classified among the geological group (Ozdemir, 2011a). Among these factors, geology is the first aspect chosen by researchers in building a GWP model, followed by lineament density (Fig. 2.5). This selection is understandable because differences in lithologies, structure, folds, and faults result in changes in the strength and permeability of soil and rock (Ozdemir, 2011a). Geology plays a significant role in finding water underground. This factor has been mentioned in many groundwater studies. From a geological perspective, groundwater exists in the fractures and voids of consolidated rock as well as in the porosity of unconsolidated sediment. Therefore, GWP research considers the water retention condition of the geological features, such as weathered products, source rocks, and unconsolidated or consolidated sediments (Xie et al., 2014). According to Termeh et al. (2019), hydraulic conductivity, porosity, and groundwater flow of an aquifer are dominated by lithology features. Assatse et al. (2016) pointed out that unconsolidated sediment rocks usually have large gaps, facilitating the existence and movement of water. Areas of unconsolidated sediment

rock have high GWP. In addition, some consolidated sediment rocks are also deemed beneficial for groundwater storage. Consolidated sediment rocks are normally sandstone and limestone (Assatse et al., 2016). In contrast, some rock types, such as metamorphic rock and volcanic rocks, are not generally considered adequate materials for good GWP. Thus, geological structure determines the existence of groundwater in a given region. To collect geological data, most groundwater studies have utilized field surveys (Bagyaraj et al., 2019) or are based on a geologic map (Zabihi et al., 2016). In addition to geological features, lineaments are also a preferential option in GWP studies. Lineaments, which are surficial expressions of faults, are an expression of underlying geological structures. Additionally, lineaments occur in the forms of fractures, lithological limits, and fault zones on the ground. Lineaments often appear in mountainous areas or straight coastlines (Adiat et al., 2012; Golla, 2020; Martha et al., 2013; Rahmati et al., 2015). In the past, lineaments were usually extracted from geology and topography maps (Moore and Waltz, 1983; O'leary et al., 1976). However, more recently, the development of space science and aerial data (such as radar, Landsat ETM (Enhanced Thematic Mapper), and Aster DEM (Digital Elevation Model)) has allowed the collection of lineaments from satellite photographs (Das et al., 2018; Hashim et al., 2013; Mwaniki et al., 2015). (Akinluyi et al., 2018) demonstrated that GWP is influenced by lineaments. Elements belonging to lineaments such as foliation, fractures, and faults are commonly used to find suitable groundwater exploitation locations. The factors related to lineament, such as distance to faults and lineament density, represent the relationship between surface and subsurface water flow through water mobility and infiltration (Termeh et al., 2019). Abdalla (2012) argued that the occurrence of faults is a good condition for groundwater recharge, especially in hard rock locations. Indeed, the fractures, joints, and lineaments act as a conduit, which strengthens the connection between surface water and groundwater. A fault zone can act as a conduit for vertical subsurface flow

or as a barrier for horizontal flow, thus making GWP poor (Bense and Person, 2006). Lineament density reflects the groundwater phenomenon under the Earth's surface. High lineament density corresponds to high secondary porosity (Haridas et al., 1998); hence, aquifers and aquitards are quickly recharged through water infiltration. Concurrently, groundwater movement and retention may be calculated via lineament density. As such, lineament data are used as an indispensable part of finding water potential underground. The first lineament data were explored in a groundwater study carried out by (Lattman and Parizek, 1964). Subsequently, many researchers have applied this approach to complex terrain areas (Abijith et al., 2020; Al-Ruzouq et al., 2019; Ali et al., 2015; Ibrahim-Bathis and Ahmed, 2016; Kamali Maskooni et al., 2020).

2.3.1.3. Hydrological-related parameters

Hydrological-related parameters play a vital role in delineating GWP zones of a given region. River density, distance to rivers, drainage, DD, distance to drainage, and net recharge are hydrological-related parameters in GWP. Among these parameters, DD and distance to rivers were more commonly used than other hydrological factors (Fig. 2.5). Rahmati et al. (2016) reported that GWP, groundwater recharge, and hydrogeological systems are affected by hydrological parameters. High groundwater productivity is rarely found in low river density areas that are far from rivers, streams, and surface water. Chen et al. (2018) indicated that surface water sources are the primary recharging sources, which affect the formation capability of groundwater springs. In addition to river-related factors, drainage-related factors also affect the GWP of an area. DD represents the drainage capacity of a basin based on the length of water flow (Bagyaraj et al., 2013; Martínez-Santos and Renard, 2020; Singh et al., 2013). DD represents residence times of groundwater (Das, 2019), where a high DD implies a large water loss capability and vice versa (Arkoprovo et al., 2012). DD is expressed by the presence of flows on the earth's surface, such as rivers and

streams. The numbers of rivers are often distributed more in delta regions than in hill regions (Mukherjee et al., 2012). DD has been directly designated as GWP; the greater this value, the higher the GWP (Nasir et al., 2018). According to Strahler (1964), DD is calculated by the overall length of rivers and outflows in a given locality divided by the total surface area of the locality. According to Moglen et al. (1998), source rock and climate features determine the shape of stream systems. Areas with a hydrology system with short and scattered rivers have a high GWP and vice versa. Ghosh et al. (2016) observed the inverse correlation of DD and permeability. The zones of high DD are associated with decreased permeability and significant surface runoff. Therefore, the GWP in these zones is low. The length factor of river and flow systems directly affects the DD of a region. In addition to the length of the flow system, other factors also impact DD, including lithology, runoff, vegetation cover, and infiltration. Therefore, DD is a necessary element in groundwater studies (Konkul et al., 2014). It is regarded as an index of groundwater recharge (Gupta and Srivastava, 2010; Mandal et al., 2016; Mosavi et al., 2020; Thapa et al., 2018). Similar to the slope, DD is usually extracted from DEM data (typically ASTER GDE, and SRTM 1 Arc Second Global satellite images with a spatial resolution of 30 m using ArcGIS 10.5 software) (Bagyaraj et al., 2013; Ibrahim-Bathis and Ahmed, 2016; Waikar and Nilawar, 2014).

2.3.1.4. Climatic-related parameters

Climatic-related parameters play a significant role in groundwater formation. In the last decade, GWP models have considered precipitation and surface temperature as determining factors in the GWP in a study area (Elewa and Qaddah, 2011; Mallick et al., 2015; Razandi et al., 2015; Shekhar and Pandey, 2015). Rainfall is a significant factor affecting groundwater recharge (Mukherjee et al., 2012; Owor et al., 2009; Shekhar and Pandey, 2015) and its occurrence (Gumma and Pavelic, 2013; Mosavi et al., 2020; Mukherjee et al., 2012; Nguyen et al., 2020b; Pham et al., 2019) in a study area. In some hydrological studies (Abijith et al., 2020; Klongvessa et al., 2018; Martínez-Santos

and Renard, 2020; Rahmati et al., 2015; Suganthi et al., 2013; Thapa et al., 2018), rainfall is also a factor that influences the recharge capacity of an area. Precipitation contributes a large amount of water to aquifers and aquitards through subsurface infiltration systems. As the rainfall increases, the groundwater level also rises (Chotpantararat et al., 2014; Shekhar and Pandey, 2015). The groundwater recharge potential is generally higher in the rainy season than in the dry season, thus increasing groundwater level (Konkul et al., 2014; Wisittammasri and Chotpantararat, 2016). This finding shows that precipitation is the water supply source for groundwater (Agarwal and Garg, 2016). In addition to the precipitation factor, Mallick et al. (2015) also utilized the surface temperature factor in the GWP study. They assumed that the heat signatures of the earth's surface help discover GWP based on specific heat. For example, dry soil has a lower heat capacity than saturated soil. The surface temperature was usually calculated from satellite imagery (Mallick et al., 2015).

2.3.1.5. Land cover-related parameters

Land use, soil type, soil depth, and NDVI are assigned to the land cover-related group in the present study. Fig. 2.5 reveals that land use and soil type are the two commonly used land cover factors by hydrologists in the past decade. Land use describes the various land-use units of humans on the earth's surface, which presents the domination of recharge rate and groundwater usage (Chen et al., 2018). Therefore, land use plays a major role in groundwater exploitation and usage (Bagyaraj et al., 2019; Dar et al., 2010; Mandal et al., 2016; Mukherjee et al., 2012; Waikar and Nilawar, 2014). Zones affected by urbanization and agricultural activities often require the exploitation of large amounts of groundwater (Odeh et al., 2019). Other zones such as forests and water bodies are rarely intervened by humans (Lone et al., 2013). Consequently, human interference directly affects groundwater storage and recharge capacity. Chen et al. (2018) reported that each land use type has a difference in water permeability. Built-up, hard rock, and bare land areas have lower

permeability than vegetation areas. Each land use type impacts groundwater retention differently based on evapotranspiration, soil erosion, and runoff (Chotpantarat and Boonkaewwan, 2018; Saravanan et al., 2018). The land use factor is routinely developed through aerial imagery and field surveys (Avtar et al., 2010; Basavaraj and Nijagunappa, 2011; Magesh et al., 2012; Mandal et al., 2016; Shekhar and Pandey, 2015). Soil type directly affects groundwater infiltration (Sun et al., 2018) and is a necessary part of defining groundwater recharge (Oh et al., 2011). Mollinedo et al. (2015) reported that a region's water holding capacity depends on the type, texture, and depth of soil. Díaz-Alcaide and Martínez-Santos (2019) indicated that gravelly and sandy soils are high percolation materials, whereas silty and clayey soils allow the least infiltration. Meanwhile, moderate infiltration is related to loamy soils and fine sand. Soil data are typically collected from available soil maps prepared by the land management department of a nation (Agarwal and Garg, 2016; Kumar et al., 2016; Oh et al., 2011; Pinto et al., 2017). NDVI is also an indicator used in forecasting groundwater storage and aquifer production of a study area (Chen et al., 2018; Naghibi et al., 2017b; Nampak et al., 2014). Areas with a high NDVI index reflect better GWP than those with a low NDVI index (Nampak et al., 2014). NDVI data are usually computed from satellite imagery sources in previous studies.

2.3.1.6. Aquifer-related parameters

In addition to geological-related factors for the formation of consolidated /unconsolidated aquifers, the other characteristics of aquifers, such as aquifer thickness, aquifer resistivity, artesian pressure, groundwater depth, and groundwater quality also influence GWP. In the groundwater study, the thickness of an aquifer also aids in defining potential zones, which is demonstrated through the thickness of weathered materials (Razandi et al., 2015). Shekhar and Pandey (2015) indicated that areas with thick weathering have more groundwater than those with thin weathering because groundwater is prevalent at the base of the weathered zone, wherein rocks

have broken down into sand size and large fragments. In addition to aquifer thickness, aquifer resistivity is also used to determine GWP in some studies (Aizebeokhai et al., 2010; Jha et al., 2010; Muchingami et al., 2012). A high resistivity value indicates low GWP and vice versa (Muchingami et al., 2012). From the viewpoint of the aquifer classification (confined/unconfined), artesian pressure is also a decisive factor in determining potential locations of groundwater. The confined aquifers occur in wide and thick permeable formations with low artesian pressure, which yields low amounts of groundwater, whereas the aquifer systems occur in thin permeable formations with high pressure, thus yielding appreciable amounts of groundwater (Da Lio et al., 2013). Groundwater depth is also one of the key indicators in determining the GWP of a well or borehole location. A large groundwater depth results in a large GWP (Machiwal et al., 2011). In addition, groundwater quality reflects the GWP of an area. Oikonomidis et al. (2015) used nitrate concentration in groundwater and GWP index to delineate GWP and non-GWP zones for domestic uses in Central Greece in the region of Thessaly. Their results indicated that groundwater in the karst area has good storage and low nitrate concentration considering a good GWP zone. By contrast, groundwater in the agricultural activity regions with high nitrate concentration is considered a poor GWP zone despite its high yield. Gopinath et al. (2019) indicated that the intrusion of seawater in eastern coastal India increases dissolved mineral concentrations (such as sodium and chloride) in aquifers due to intensive pumping rates. This phenomenon reduces GWP in areas facing seawater intrusion problems. Furthermore, Chotpantarot et al. (2020) used hydrochemical characteristics, including the stable isotopes ^{18}O and ^2H , to assess the origin of the groundwater and applied principal component analysis to determine sources of nitrate contamination in Phetchaburi Province, Thailand. Their result showed that nitrate concentration mainly originated from the agricultural regions, reducing the GWP area in this region. Boonkaewwan et al. (2020) investigated the mechanisms of arsenic (As) release in coastal alluvial aquifers in Rayong Province,

Thailand. They found that arsenite (As^{3+}) is mainly released in the deep coastal aquifer groundwater due to reducing conditions. Thus, groundwater treatment is necessary for some areas before drinking. As previously mentioned, in addition to the groundwater quantity, the assessment of the GWP area should also consider groundwater quality.

2.3.2. Model techniques

Approximately 59% of the 91 publications (Table 2.1) used a model or method to develop and assess GWP. The remaining 31% used two or more models. The current study classified the models into three main groups: statistical, machine learning, and hybrid/ensemble models (Fig. 2.6). The model categorization was complicated, and many revisions were made until the final categorization was realized; this categorization was subjective and based on expert judgment. Fig. 2.6 shows the information regarding the popularity of models used in 91 publications. The database of this study revealed the use of 60 models from 2010 to 2020; the figure is considerably large. Models MCDA-AHP, FR, EBF, WOE are the models with the most occurrences in the statistical group, while RF, LR, BRT, SVM models are used a lot in machine learning group. In this section, the study looks into the characteristics and roles of these popular models.

combined with GIS tools, verifying the geographical regions that agree with GWP conditions. The MCDM-AHP model is typically used to evaluate GWP comprising the following four steps. Step 1: Establishing the factors related to the GWP and creating an important hierarchy for factors. Step 2: Classifying and comparing the factors influencing groundwater. Step 3: Calculating the weighted value of the influencing factors. Step 4: Validating the consistency of the pair comparisons. In the MCDM-AHP, influence factors are combined into an indicator to evaluate outputs ([Andualem and Demeke, 2019](#)).

In recent years, hydrological studies have commonly applied the MCDM-AHP model. [Elmahdy and Mohamed \(2014\)](#) delineated GWP zones using the AHP model in the Al Dhaid area, United Arab Emirates. The model was successful in integrating thematic layers and assessing their weights. [Selvam et al. \(2015\)](#) created GWP and recharged zones in the Tuticorin districts of Tamil Nadu, India, using the MCDM technique. The variables used included soil, precipitation, slope, drainage, lithology, land use, and lineaments, where lithology and land use were integrated with the highest weight. [Jenifer and Jha \(2017\)](#) used the MCDA-AHP model for mapping GWP zones in the state of Tamil Nadu of India based on the assigned weights of thematic layers according to the suggestion of experts. The AHP model provided accurate predictions. The groundwater yield was applied to test the validity of the AHP model. [Andualem and Demeke \(2019\)](#) incorporated the MCDM technique and GIS technology to delineate the GWP zones in Upper Blue Nile Basin, Ethiopia. The thematic layers were assigned on the basis of the standardization with effective potential. The results indicated that GWP was categorized into the following five zones: excellent, very good, moderate, poor, and very poor potential fields. Simultaneously, [Arabameri et al. \(2019\)](#) found that the AHP model was more effective than the random forest model by using yield data and thematic layers to assess GWP.

b. Frequency ratio (FR) model

The FR model is applied mainly in landslide research. This model is utilized to assess and predict the landslide locations in a given region (Choi et al., 2012; Jaafari et al., 2014; Pradhan, 2010). In recent years, some hydrogeologists have used the FR model to research groundwater resources (Falah et al., 2017; Guru et al., 2017; Mousavi et al., 2017; Termeh et al., 2019). The FR model is a bivariate statistical algorithm used to compute the occurrence probability rate of a factor (Razandi et al., 2015). Thus, the FR ratio is the rate of non-occurrence or occurrence of a given characteristic. Regarding advantages, the FR is a simple method used to compute the probabilistic connection between the environmental factors and GWP. This method helps discover the spatial correlations between GWP and environmental factors and simplifies the quantification and comprehension of each environmental factor by the model. The FR model is directly employed in a GIS (Oh et al., 2011), and its outcomes are uncomplicated (Falah et al., 2017). However, the FR model depends on the technique-related elements. The adjustment of input parameters will impact the output map (Oh et al., 2011). In reality, the construction of the FR model is conducted on the basis of the observed interactions between each groundwater conditioning factor and the distribution of groundwater well/spring sites.

In the last decade, many studies have conducted GWP maps utilizing the FR model. Ozdemir (2011b) discovered that the FR model was better estimators than Weights of evidence (WOE) and Logistic regression (LR) in mapping GWP in the Sultan Mountains, Turkey. Oh et al. (2011) used the FR model to create the GWP map in the area of Pohang City, Korea. They surveyed 83 well locations; the well points at 55 locations were used for training the model, and the well points at 28 locations were selected for the model test. The training cases were utilized to predict the groundwater appearance availability based on thematic layers, including soil, lineament, geology, and topography data. Their result indicated that soil texture had

the most impact on GWP, whereas ground elevation had the least impact. [Razandi et al. \(2015\)](#) compared the efficiency of the FR, AHP, and gradient boosted decision tree (DT) models in Varamin Plain, Iran, with the areas under the curves (AUCs) of 77.55%, 73.47%, and 65.08%, respectively. [Guru et al. \(2017\)](#) applied the FR to explore the impact of six factors (i.e., DD, lineament density, geology, slope, geomorphology, and land use) on groundwater level. The prediction rate of the FR model was 77.23%. According to [Termeh et al. \(2019\)](#), the FR model was used to create the groundwater spring potential map in Alborz, Iran. They surveyed 339 springs; springs at 238 locations were used for training the model, and springs at 101 locations were selected for the model test. The training cases were utilized to predict the groundwater appearance availability based on thematic layers, including land cover, lithology, DD, fault density, topographic wetness index, plan curvature, slope direction, altitude, soil, precipitation, distance from the river, distance from the fault, profile curvature, slope length, and slope angle.

c. Evidential belief function (EBF) model

The EBF is a bivariate statistic model based on the combination rule to determine spatial integration ([Naghibi and Pourghasemi, 2015](#)). The structure of an EBF model includes degree of plausibility (Pls), degree of uncertainty (Unc), degree of disbelief (Dis), and degree of belief (Bel) ([Nampak et al., 2014](#)). The Pls and Bel are respectively upper and lower levels of belief with a basic probability assignment function. The Unc is equal to Pls-Bel, which is a lack of understanding evidence of a proposition. The Dis is a value of $1 - \text{Pls}$ that ranges from 0 to 1, which is the belief of a false proposition. The relative flexibility of EBF is used in the GWP study to admit uncertainty of spring occurrence from the available evidence ([Naghibi and Pourghasemi, 2015](#)). However, the FR requires a considerable amount of information to reduce uncertainty.

Recent GWP projects indicate that the EBF provides a reasonable solution for conceptual methods. [Manap et al. \(2014\)](#) applied the EBF model to investigate groundwater productivity at Langat basin area, Malaysia. The input database included the potential of 12 environmental factors: rainfall, soil, NDVI, land use, lineament density, lithology, DD, TWI, SPI, curvature, slope, and elevation. The main goal was to delineate groundwater productivity zonation and demonstrate the value of the EBF model. [Naghibi and Pourghasemi \(2015\)](#) compared the performance of the EBF to that of the Boosted regression tree (BRT), CART, Random forest (RF), and GLM models using land use, lithology, fault density, river density, distance to faults, distance to rivers, TWI, SPI, slope length, profile curvature, plan curvature, elevation, slope aspect, and slope angle as the environmental factors to map GWP in Chaharmahal-e-Bakhtiari Province, Iran. The assessment output indicated that the performance of the EBF was the lowest among the models. [Tahmassebi-poor et al. \(2016\)](#) investigated the GWP with the EBF and WOE approaches. The input factors were utilized as precipitation, lineament density, slope percent, TWI, curvature, elevation, DD, soil texture, distance from river, land use, and lithology. The result showed that the AUC of the EBF and WOE was 83.7% and 78.2%, respectively. [Kordestani et al. \(2019\)](#) simulated GWP in Chaharmahal-e-Bakhtiari Province, Iran by combining the EBF and the BRT, namely the EBF-BRT model. The inputs included topographical and hydrogeological factors. The results revealed that the EBF-BRT was more accurate than the EBF. In another research project, [Termeh et al. \(2019\)](#) compared the ANFIS-GA (genetic algorithm), ANFIS-BBO, ANFIS-SA (simulated annealing), FR, EBF, and entropy models for predicting GWP in Booshehr plain, Iran. They concluded that the ANFIS-GA had superior performance to other models.

d. Weights of evidence (WOE) model

The WOE technique is a method that uses phenomena and events to prove a hypothesis ([Al-Abadi, 2015](#); [Falah et al., 2017](#); [Oikonomidis et al., 2015](#); [Ozdemir,](#)

2011b). This method evaluates the weight of variables based on the probability of a phenomenon or event occurring on each variable. This model is derived from the weight of evidence method used in Bayesian statistics. In GWP studies, the WOE estimates the weight for the absence or presence of each subclass of environmental factors based on the absence or presence of representative parameters, such as groundwater yield and spring/well/borehole occurrence, within a given region (Al-Abadi, 2015; Falah et al., 2017; Oikonomidis et al., 2015; Tahmassebi et al., 2016). The advantages and disadvantages of the WOE lists are as follows. On the one hand, the WOE helps eliminate the subjectivity of weight and easily sets up the GWP maps. On the other hand, the WOE depends on the number of conditioning variables to set the weight of evidence and require the independence of data input (Tahmassebi et al., 2016). Therefore, a requirement for studies using the WOE is to determine the accurate number of input variables, which helps obtain the correct weight of variables in the model.

While researching groundwater productivity potential mapping, Lee et al. (2012) analyzed the correlation of hydrogeological factors with specific capacity (SPC) and transmissivity (T) data. SPC and T were collected at 83 and 81 well locations in Pohang city, South Korea, respectively. SPC and T data were subdivided in a 70:30 ratio to train and validate the output. They concluded that the WOE model's accuracy was 71.20%. The map was generated by the WOE model with relatively accurate groundwater resource exploration. Al-Abadi (2015) applied the WOE model to demarcate GWP in the Missan and Wasit governorates, Iraq. This study utilized data from 143 borehole locations and eight variables affecting GWP, including depth of borehole, aquifer type, distance to faults, distance to roads, LU, geology, slope, and altitude. The results of the GWP map were divided into areas with very high potential (15%), areas with high potential (23%), areas with medium potential (32%), and areas with low potential (30%). Falah et al. (2017) investigated the capabilities of

the WOE, GAM, FR, and SI with different combinations of land use, soil, lithology, distance to faults, fault density, topographic wetness index, distance to rivers, DD, slope aspect, slope angle, plan curvature, altitude, and 6439 springs to predict GWP in Lorestan Province, Iran. Their results showed that the accuracy of the GWP delineation map from the WOE was lower than that of other models. [Chen et al. \(2018\)](#) developed a novel ensemble WOE with LR and functional tree models to map groundwater spring potential in Shaanxi Province of China. They found that the ensemble model is more satisfactory compared with individual models. [Falah and Zeinivand \(2019\)](#) applied the WOE model to compare it with an FR model in the assessment of groundwater distribution in Lorestan province, Iran. They used 212 springs, in which 140 springs were training datasets and 72 springs were test data. Their output data showed that the predictions of the WOE model are less accurate than those of the FR model.

2.3.2.2. Common machine-learning models

a. Random Forest (RF) model

The random forest (RF) is a predictive model that uses many DTs to forecast the appearance of an event, in which each DT is generated from resampling. In 2001, [Breiman \(2001\)](#) was the first author to apply the RF algorithm to classify his data. Then, the RF was further developed and utilized in many science fields. According to [Rodriguez-Galiano et al. \(2014\)](#), regression trees and classification trees could be considered part of the RF model. A regression tree mission involves determining the limitation characteristics and conditions for the formation of a node in a DT, while the function of the classification tree is to classify the data that have not been previously categorized into appropriate groups or classes. The RF model yields very high accuracy results but does not show the operating algorithms because of the complex structure of this model ([Rodriguez-Galiano et al., 2014](#)). The output of RF

can be classification or regression. The RF has pros and cons compared with other machine learning models. Regarding advantages, the RF can work with complex data, decrease the overfitting and variance issues, and is remarkably stable. Meanwhile, the disadvantages of the RF lie in its large and powerful computer resource requirement, long training process, and its assignment of the number of variables and trees in the model.

In the area of GWP with the RF, [Zabihi et al. \(2016\)](#) assessed two GWP maps created with RF and MARS for Boujnordm, North Khorasan, Iran. Fourteen explanatory factors and 234 spring locations, including 176 cases, were applied to train the model, and 58 locations were employed to create the GWP. The result showed that the AUC of RF is lower than the AUC of MARS. Similarly, [Golkarian et al. \(2018\)](#) compared the RF, C.50, and MARS in forecasting GWP in Mashhad, Razavi Khorasan Province, Iran. The input variables were lithology, land use, faults density, rivers density, distance to faults, distance to rivers, slope length, TWI, profile curvature, plan curvature, slope angle, slope aspect, and elevation. Their outcome indicated that the RF had an accuracy lower than MARS and higher than the C5.0. [Naghibi et al. \(2018\)](#) compared the KNN, ANN, PDA, QDA, LDA, Support vector machine (SVM), MARS, BRT, and RF models for GWP assessment in Iran. Lithology, land use, fault density, river density, distance from faults, distance from rivers, TWI, SPI, slope length, slope curvature, plan curvature, slope aspect, and altitude were utilized as the input factors of these models. They indicated that the RF was the best among all models in mapping GPW, and four factors with the most impact on GWP included profile curvature, plan curvature, slope, and elevation. [Naghibi et al. \(2019\)](#) simulated GWP by using the RF, CART, BRT, EBFTM, and RTF. They used 13 input factors, including lithology, land use, fault density, distance from faults, river density, distance from rivers, TWI, slope length, profile curvature, plan curvature, altitude, slope aspect, and slope angle, and 273 spring locations. They concluded that the

EBFTM had the highest performance, followed by the RF. [Pham et al. \(2019\)](#) indicated that the RF was a useful model for predicting groundwater spring potential; hence, the maps created by this model could be advantageous for groundwater resource exploration and management.

b. Logistic regression (LR) model

The LR model is commonly used in research on water issue prediction. This model has recently been developed in other groundwater-related areas, such as ground subsidence ([Oh et al., 2011](#)) and potential groundwater springs ([Nampak et al., 2014](#); [Ozdemir, 2011b](#); [Rahmati et al., 2018](#)). The LR is a regression model that finds the correlation between independent and dependent parameters to create the coefficient ([Nguyen et al., 2020b](#)). The result of the LR is only 0 or 1 (binary model). The LR is helpful in GWP studies to predict groundwater absence or presence via spring/non-spring specific yield parameters. Similar to other machine learning models, the LR has the advantages of simplicity and linearity and is reliable in data training. The disadvantage of the LR is easily gotten overfitting as the number of features is higher than that of observation. Additionally, the LR requires the dependent variable that must be the discrete number set and cannot process non-linear problems.

[Ozdemir \(2011b\)](#) created a groundwater spring potential map (GWSP) for the Sultan Mountains, Turkey, integrating an LR model with the GIS environment. The validation of the research surveyed 440 springs and 17 spring-related variables. The authors reported that this was the first study on GWP using an LR approach to identify potential regions of groundwater. The coefficient of 17 spring-related variables was calculated using the binary LR method. The results show that the LR model is a suitable tool to estimate GWSP in a given region. [Nampak et al. \(2014\)](#) compared the LR and the EBF in predicting GWP in Malaysia's Langat River catchment. They considered precipitation, soil type, NDVI, land use, lineament

density, lithology, DD, TWI, SPI, curvature, slope, and elevation as input factors and concluded that the EBF outperformed the LR. [Rahmati et al. \(2018\)](#) used the LR with the DT to map GWP in Khorasan Province, Iran and compared it with the SVM and C4.5 models. The inputs to the models were CI, slope, TPI, TWI, RSP, stream density, distance from stream, lithology, distance to fault, aspect, and elevation. The results indicated that the LR had the highest AUC value, followed by the SVM and C4.5 models. [Zandi et al. \(2016\)](#) applied the LR to map GWP. They used 38 springs to train the model with mean precipitation, land use, relative, fault density, fault distance, petrology, and slope. After the training, the output map was tested through the AUC value. They concluded that the LR was an effective model in mapping GWP. From the results, land use was the environmental factor that impact the highest on GWP. [Martinez-Santos and Renard \(2020\)](#) successfully demonstrated the efficiency of the LR model in the Bauole sub-catchment, Mali, using precipitation, land use, soil, NDVI, TWI, slope, DD, lithology, proximity to surface water, lineament density, and lineaments and 1848 borehole yields.

c. Boosted regression tree (BRT) model

The BRT is a combination model between the boosting method and the DT algorithm. The BRT operates by combining and fitting many DTs based on the boosting method to improve the predictive performance. The output of BRT is an average model from many approximate rules, but boosting is conducted in a stepwise procedure ([Nampak et al., 2014](#)). The application of BRT in GWP mapping is compatible with classification and regression of a spring/non-spring location or groundwater yield in a given region ([Mousavi et al., 2017](#); [Naghbi and Pourghasemi, 2015](#); [Nampak et al., 2014](#)). Considering its advantages and disadvantages, the BRT can work with numerical and categorical data, reduce overfitting, and optimize the different loss functions. However, the real-time database process of the BRT is long because of the large number of trees, and the output can be outliers.

[Naghibi et al. \(2016\)](#) compared the performance of the BRT to that of the CART, RF, and EBFTM in the spatial modeling of GWP. They used 864 spring locations to train and validate these models according to the rate of 70:30. The input factors included fault density, DD, land use, geology, distance to faults, distance to rivers, profile curvature, plan curvature, slope length, TWI, altitude, slope aspect, and slope degree. Their result showed that the BRT was a good model in predicting GWP with an AUC value of 0.898. [Mousavi et al. \(2017\)](#) used the BRT and the FR to delineate GWP zones in the Mashhad Plain, Iran. Lithology, land use, fault density, river density, distance to rivers, distance from faults, TWI, slope length, profile curvature, plan curvature, elevation, slope aspect, and slope degree were applied as input factors. Both models demonstrated satisfactory performances. Their results showed that TWI had the largest impact on predicting GWP, followed by elevation and distance to rivers. [Al-Abadi \(2017b\)](#) compared the BRT with FR and the ant miner algorithm in assessing GWP in the Euphrates River Basin, Iraq. The slope, profile curvature, plan curvature, TWI, SPI, distance to rivers, distance to faults, altitude, lithology, and aquifer type were used as the input data of these models. The result indicated that the GWP map from the ant miner algorithm was more accurate than that from the BRT and the FR. [Kim et al. \(2019\)](#) investigated the capabilities of the BRT, RF, and LR in predicting specific capacity and transmissivity of groundwater productivity in the Okcheon-gun, South Korea, by using the inputs of plan curvature, convergence index, TRI, depth of groundwater, distance from channel network, distance to faults, lineament density, drainage basin, slope length, TWI, valley depth, relative, slope, soil type, land use, and geology. Their results showed that applying the BRT, RF, and LR with specific capacity and transmissivity had high accuracy.

d. Support vector machine (SVM) model

The SVM is a statistical learning model for regression and classification tasks to determine a hyperplane for training data ([Rahmati et al., 2018](#)). The SVM

comprises sigmoid kernels, radial basis function, polynomial, and linear (Rahmati et al., 2018). In the GWP, the SVM considers the environmental factors as the x variable and the validation factors (groundwater yield, specific capacity, and spring/non-spring) as the class label. The optimal separating hyperplane helps classify the training data into subsets or classes (+1, -1) (Lee et al., 2018; Naghibi et al., 2017a; Naghibi et al., 2018; Sameen et al., 2019). The advantage of the SVM lies in its effective operation in high-dimensional spaces and in cases where the number of samples is lower than that of dimensions. However, the SVM underperforms when the dataset is large and the noise is substantial.

Naghibi et al. (2017a) tested four different SVM models along with the random forest genetic algorithm optimized (RFGA) and the RF to create the GWP maps in Ardebil Province, Iran. The environmental factors included lithology, land use, faults density, distance to faults, rivers density, distance from rivers, TWI, SPI, profile curvature, plan curvature, slope aspect, slope angle, and elevation. SVM yielded the best result among different SVMs. However, the performance of all SVM models was lower than the RF and the RFGA. Lee et al. (2018) compared the ANN and SVM for GWP prediction in Boryeong City, Korea. They used 27 hydrogeological factors to predict groundwater yield and SPC. Their results revealed that the ANN was better than the SVM in performance. However, the SVM was proposed as a time-effective GWP tool. Guzman et al. (2019) investigated GW for agricultural activities in the southeastern USA. They considered evapotranspiration, precipitation, and groundwater level data as model input. Their results concluded that the SVR was better than the ANN. Sameen et al. (2019) applied the RF, SVM, ANN, DT, SLRF, and voted ANN-RF to map GWP. The applied data included geology, profile curvature, TWI, STI, SPI, elevation, aspect, slope, curvature, plan curvature, distance to stream, land use, and TRI and 85 wells with different groundwater yields to train and test these models. The comparison between the RF, SVM, ANN, DT, self-learning random

forest (SLRF), and voted ANN-RF for GWP mapping indicated that the SLRF was the most suitable model. [Panahi et al. \(2020\)](#) applied the SVM with grid search and genetic algorithms to forecast GWP in the Ajloun and Jerash Provinces, Jordan. The models were applied to improve the predictive performance in GWP using environmental factors, including NDVI, lithology, land use, rainfall, distance to faults, slope length, soil type, SPI, distance to drainage, TWI, curvature, altitude, aspect, and slope angle. Their results indicated that applying the SVM with the genetic algorithm demonstrated more accuracy than the SVM with the grid search.

2.3.2.3. Hybrid/ensemble models

The evolution of computer science, GIS, and remote sensing has helped models overcome the disadvantages and improve predictive performance. Combined or hybrid models have commonly been used in GWP studies in recent years. The combination of statistical methods and machine learning not only solves data problems but also boosts the predictive productivity of GWP. Additionally, the integration of parametric and nonparametric structures from different sources of knowledge is a strong point of the hybrid/ensemble models. This finding has been demonstrated in many recent GWP studies using hybrid/ensemble models. [Khosravi et al. \(2018\)](#) delineated GWP zones in the Koohdasht–Nourabad Plain in Iran by integrating ANFIS with metaheuristic optimization algorithms. They used lithology, soil type, rainfall, land use, distance from river, distance from fault, TRI, TWI, SPI, plan curvature, elevation, and slope as input data. IWO, DE, FA, PSO, and BA algorithms were applied to optimize the ANFIS. Their result revealed that the ANFIS + DE demonstrated the best model performance. [Termeh et al. \(2019\)](#) proposed a combination between SA, BBO, and GA techniques and ANFIS to optimize the GWP map. The relevant input factors include land use, soil, rainfall, lithology, distance to rivers, fault density, distance to faults, DD, TWI, profile curvature, plan curvature, slope length, slope aspect, slope angle, and altitude. A total of 339 wells were

divided with a scale of 70:30 to train and validate these models. The GA was found to be superior to the SA and BBO method as combined with ANFIS for improving the performance of the GWP map. These models also indicated that rainfall, soil, and land use were important factors for GWP in the Booshehr plain, Iran. [Pham et al. \(2019\)](#) investigated the GWP in the Vadodara district, India, by developing hybrid models based on Decision Stump (DS), RF, MB, and BG. Their database included 34 groundwater wells, slope, soil, land use, lithology, river density, precipitation, TWI, plan curvature, aspect, slope, and altitude. They also integrated DS with other models to classify the different ensemble learners. Their result indicated that the dataset with a scale of 50:50 is superior to other ratios, and the performance of all hybrid models was satisfactory. [Singh et al. \(2022\)](#) created a hybrid model based on catastrophe theory (CT) and AHP to analyze the space of GWP in the West Bengal state, India. Their result removed the major limitation of the catastrophe theory in quantitative factors. The accuracy of this hybrid model was 77%. [Nguyen et al. \(2020b\)](#) developed four ensemble models using LR with cascade generalization, random subspace, bagging, and dagging to map the GWP in Dak Lak Province, Vietnam. They used 12 geo-environmental factors, such as geology, land use, soil, river density, precipitation, flow direction, TWI, STI, curvature, slope, elevation, and aspect, and the groundwater yield of 195 well locations, as input data. Their result revealed that the AUC value of ensemble models was higher than that of the single LR model, in which the LR+ dagging demonstrated the best performance.

2.3.3. Validation

2.3.3.1. Validation-related parameters

The past studies ([Machiwal et al., 2011](#); [Naghibi and Pourghasemi, 2015](#); [Rajaveni et al., 2017](#); [Razandi et al., 2015](#)) have applied the groundwater measurement parameters, such as specific yield (Sy)/specific storage (Ss), non-spring/spring occurrence,

and groundwater level, to delineate the GWP zones of a given region. [Uliana \(2005\)](#) stated that “specific storage (Ss) is the volume of water released from a unit volume of a confined aquifer for a unit (1 m or 1 ft) drop in piezometric head, and specific yield (Sy) is the volume of water that can yield by gravity drainage from a unit volume of an unconfined aquifer for a unit drop (1 m or 1 ft) in water level; this quantity is equivalent to the effective porosity.” [Kresic \(2010\)](#) indicated that spring is a location where groundwater is discharged to the land surface by gravity and water pressure. The groundwater level is the level of saturated water in soil or rock observed in a well/borehole ([Maggirwar et al., 2011](#)). These parameters are crucial for classifying the GWP levels of a given area. The GWP studies from 2010 to 2020 have used different parameters depending on reality conditions and approaches to develop and assess the models. [Machiwal et al. \(2011\)](#) indicated that the high GWP is associated with a large groundwater yield. Specifically, the areas with good GWP have a groundwater yield larger than 5 m³/h, the areas with medium GWP have groundwater yield ranging from 1 m³/h to 5 m³/h, and those with low GWP have a groundwater yield of less than 1 m³/h. [Razandi et al. \(2015\)](#) conducted a study in the Varamin Plain, Iran and found that wells with groundwater yield of more than 40 m³/h are known as locations with good groundwater productivity. [Ozdemir \(2011a\)](#) used the non-spring/spring occurrence to determine the GWP levels in Aksehir, Turkey. Locations with spring occurrence were reported to have good groundwater productivity. Non-spring/spring occurrence was also used in the research by [Naghbi and Pourghasemi \(2015\)](#) to delineate GWP zones in the Chaharmahal-e-Bakhtiari Province, Iran. Their result revealed that springs rarely occur in regions with low GWP. [Rajaveni et al. \(2017\)](#) indicated that the groundwater level in a well/borehole also represents GWP at a location. They found that areas with low GWP have large groundwater fluctuations, while areas with high GWP have low groundwater fluctuations. [Mukherjee et al. \(2012\)](#) observed data on groundwater levels to verify the GWP map in Kachchh district, India.

2.3.3.2. Validation technique

Validation is a crucial step in assessing GWP models. Validation testing generally verifies forecast performance. [Rajae et al. \(2019\)](#) indicated that the predicted results increasingly improved. Algorithm development in models has increased, aided by the evolution of GIS, RS, machine learning technologies. [Díaz-Alcaide and Martínez-Santos \(2019\)](#) also argued that the reason for the increased predictive efficiency is the use of an increased number of variables in GWP mapping. According to statistics from the study dataset (91 publications), four main techniques used by hydrogeologists in groundwater research to check the accuracy of a groundwater map in their area of interest are as follows: receiver operating characteristic (ROC), statistical evaluation measures, Kappa index, and root mean square error ([Table 2.2](#)). Among these techniques, the ROC is mostly used in GWP studies with model performance evaluation. The choice of the groundwater map validation technique depends on the preference of the operator. Performance evaluation results for common models in this study are shown in [Fig. 2.7](#).

Fig. 2.7. Fluctuation of AUC value in common models in GWP studies

Table 2.2. Validation methods in GWP studies

No	Validation method	Descriptions	References
1	Receiver operating characteristic	<p>The ROC is a curve line graph that describes the relationship between sensitivity (Y-axis) and 1-specificity (X-axis) for every possible cutoff value.</p> <p>The value of ROC is the under-curve area ranging from 0.5 to 1. (0.5-0.6: poor; 0.6-0.7: average; 0.7-0.8: good; 0.8-0.9: very good; 0.9-1: excellent).</p>	(Naghibi et al., 2017a)
2	Statistical evaluation measures	$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN}$ $\text{Sensitivity analysis} = \frac{TP}{TP+FN}$ $\text{Specificity analysis} = \frac{TN}{TN+FP}$ <p>where TP – true positive; TN – true negative; FP</p>	(Nguyen et al., 2020b)

		Kappa coefficient is an index to calculate the model reliability in GWP classification.	
3	Kappa coefficient	$\text{Kappa} = \frac{\text{Accuracy} - P_e}{1 - P_e}$ <p>P_e is an agreement level that might be generated by chance. The closer the kappa value gets to 1, the better model's performance is.</p>	(Golkarian et al., 2018)
4	Root mean square error	<p>Root mean square is a value that measures the deviations of all samples between the predicted value (X_p) and the actual value (X_a).</p> $\text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n (X_p - X_a)^2}$ <p>The closer the RMSE value is to 0, the better model's performance is.</p>	(Rahmati and Melesse, 2016)

2.4. Current status and challenges for groundwater potential mapping research in the future

This review provides an overview of factors pertaining to GWP mapping from model thematic layers, algorithms, and their accuracy. A GWP map must present the potential areas of groundwater (Elmahdy and Mohamed, 2014). Hydrogeologists usually delineate their potential maps into five levels: very high, high, moderate, poor, and very poor potential regions (Kumar et al., 2014; Mukherjee et al., 2012; Pham et al., 2019). According to the statistics of this review, there are eight topical map layers commonly used by hydrogeologists: geology, slope, land use, soil type, drainage density, lineament density, altitude, rainfall.

Another consideration of GWP map is the data source for mapping thematic layers. For data sources to create thematic layers, two main sources have been commonly employed: satellite data and hydrogeological data. Today, the development of RS technology has provided a large amount of data on the Earth's

surface and weather information, facilitating map creation within a shorter time than that required for field data collection (Díaz-Alcaide and Martínez-Santos, 2019). Thus, although RS data are effective, scientists must have a wide and in-depth knowledge of RS (Oikonomidis et al., 2015). Some satellites with high resolution provide high-quality images; however, this makes the images cost-intensive making their use unfeasible. Another disadvantage of RS data is that satellite images only provide coverage information; information of objects present under cloud cover and treetops is not considered. This requires hydrogeologists to combine information from the field, such as the borehole, well, and hydrogeological data, with RS; field parameters can provide what RS data cannot. For example, well productivity data cannot be collected from satellite images. Additionally, field data always provide a high degree of confidence and validity. However, the collection of borehole, well, and hydrogeological data is time- and labor-consuming. According to current statistics, there are several approaches to establish a GWP map. These methods can be divided into three groups: statistical, machine learning, hybrid/ensemble techniques. The common statistical techniques include MCDA-AHP, FR, EBF, and WOE models. The features of the statistical models are easy to implement a GWP map, their observed variables do not require more than that of machine learning models. In some cases, several authors have only used the weights of the affected variables of groundwater, ignoring the map's accuracy (Gaur et al., 2011; Hashim et al., 2013; Murmu et al., 2019; Singh et al., 2013). Recently, machine learning models have been used extensively by hydrogeologists. The common machine learning models include RF, LR, BRT, and SVM. Big data are required to train and test the machine learning models (Martínez-Santos and Renard, 2020). From basic machine learning and statistical models, hydrogeologists have developed advanced models aimed at creating more accurate GWP maps such as the adaptive neuro-fuzzy inference system (ANFIS) + differential evolution (DE) model (Khosravi et al., 2018), random

forest (RF) + decision Strump (DS) (Pham et al., 2019), adaptive neuro-fuzzy inference system (ANFIS) + genetic algorithm (GA) (Termeh et al., 2019), and logistic regression (LR) + dagging (DLR) (Nguyen et al., 2020b).

An integral part of any GWP study is the validation step (Das, 2019). Statistically, receiver operating characteristic (ROC), statistical evaluation measures, Kappa index, and root mean square error are four main techniques used to evaluate a GWP map. Statistical evaluation measures, Kappa index, and root mean square error are often used to check the accuracy of statistical models, while the AUC technique is often used to check the accuracy of machine learning models and several statistical models. Generally, the effectiveness of the common statistical models ranges from approximately 59.0% to 90.3% while the accuracy of GWP maps produced by common machine-learning models goes from 50.0% to 90.1%. Strikingly, a higher accuracy interval (71.0% - 92.0%) was shown in the hybrid/ensemble models (Fig. 2.7). In addition, some authors have combined the AUC technique with specificity, sensitivity, negative predictive value, and the positive predictive value (Nguyen et al., 2020b; Ozdemir, 2011a; Pham et al., 2019).

The complex changes in climatic conditions and an increase in the demand for clean water pose many challenges for hydrogeologists with regard to groundwater use and planning. In reality, hydrogeologists have conducted extensive researches and pursued various methods and approaches to create the most suitable GWP map for their regions of interest in the past decade. However, GWP mapping research is still characterized by a number of limitations and challenges that need to be addressed in the future.

Thus far, researchers have not found the optimal models required to map the GWP of different areas around the world. There are two reasons for this: the difference between regions in natural conditions and social characteristics, and the discrepancy in the input data. Therefore, it is difficult to conclude which model is the most accurate. Simultaneously, the constant changes in climatic conditions, runoff factors, land-use

coefficients, and population growth directly affect the GWP of a certain region, posing great difficulties for hydrogeologists in mapping GWP.

To address these challenges, future research should focus on the following aspects. First, studies must focus on improving the quality and quantity of the input database to ensure the reliability of GWP maps. At the same time, stronger emphasis must be placed on using satellite images with high resolution to improve the accuracy of classification, which will lead to the improved accuracy of the forecast results. Third, maps should be created based on a combination of machine learning and statistical models. Fourth, researchers need to apply different approaches for each research region to acquire the most suitable research model. Finally, three-dimensional models should be used to obtain an overview of the groundwater system.

2.5. Summary

This chapter aims to review parameters, model techniques, validation methods in groundwater potential field. According to statistics, there are three major model groups used to establish groundwater potential maps. The first model group is a statistic group, including multi-criteria decision making/analytic hierarchy process, frequency ratio, evidence belief function, and weights of evidence. The second model group includes machine learning models, such as random forest, logistic regression, boosted regression tree, and support vector machine. The final group is the hybrid/ensemble models. In groundwater potential mapping studies, 41 thematic layers affect the potential of groundwater. However, hydrological researchers have frequently used eight factors in groundwater potential studies: geology, slope, land use, soil type, drainage density, lineament density, altitude, rainfall. Most previous studies on groundwater potential have used a combination of geographic information system, remote sensing, and machine learning techniques to design the groundwater potential in regions of interest. Data sources are commonly applied to groundwater potential mapping, including satellite, borehole, and geophysical data. The

accuracy of groundwater potential maps produced by common machine learning models ranges from 50.0% to 90.1%, while that produced by common statistical models ranges between 59.0% and 90.3%. Interestingly, hybrid/ensemble models' accuracy interval was from 71.0% to 92.0%. Therefore, the review suggests that statistical algorithms and machine learning techniques should be combined, and thematic layers should be increasingly used in mapping groundwater potential maps to achieve high efficiency.

Chapter 3. STUDY AREA AND RESEARCH METHODOLOGIES

3.1. Study area

3.1.1. Location

The present study focuses on the distribution of potential groundwater in Kanchanaburi province, Thailand. The province is placed in the western central of Thailand, from 99°10'54'' to 99°53'31''E and 13°43'34'' to 15°39'46''N (Fig. 3.1). There are approximately 19,483 km², of which 61% is a mountain with an elevation from 2 m to 2,028 meters (6653 ft) above sea level. The province has 847.47 km long of the border with neighboring provinces and Myanmar. The region has a tropical savanna climate with significant seasonal variations in temperature and precipitation. Administratively, Kanchanaburi is separated into 13 districts: Bo Phloi, Dan Makham Tia, Huai Krachao, Lao Khwan, Mueang Kanchanaburi, Nong Prue, Phanom Thuan, Sai Yok, Sangkhla Buri, Si Sawat, Tha Maka, Tha Muang, and Thong Pha Phum.

Fig. 3.1. Location of Kanchanaburi province

As of December 31st, 2018, the number of inhabitants of Kanchanaburi was 848,198 and, the population density was around 43.5 people/km² (the Statistical Yearbook of Thailand 2018). Four population groups are living in Kanchanaburi, including Thai, Karen and Mon, and Burmese.

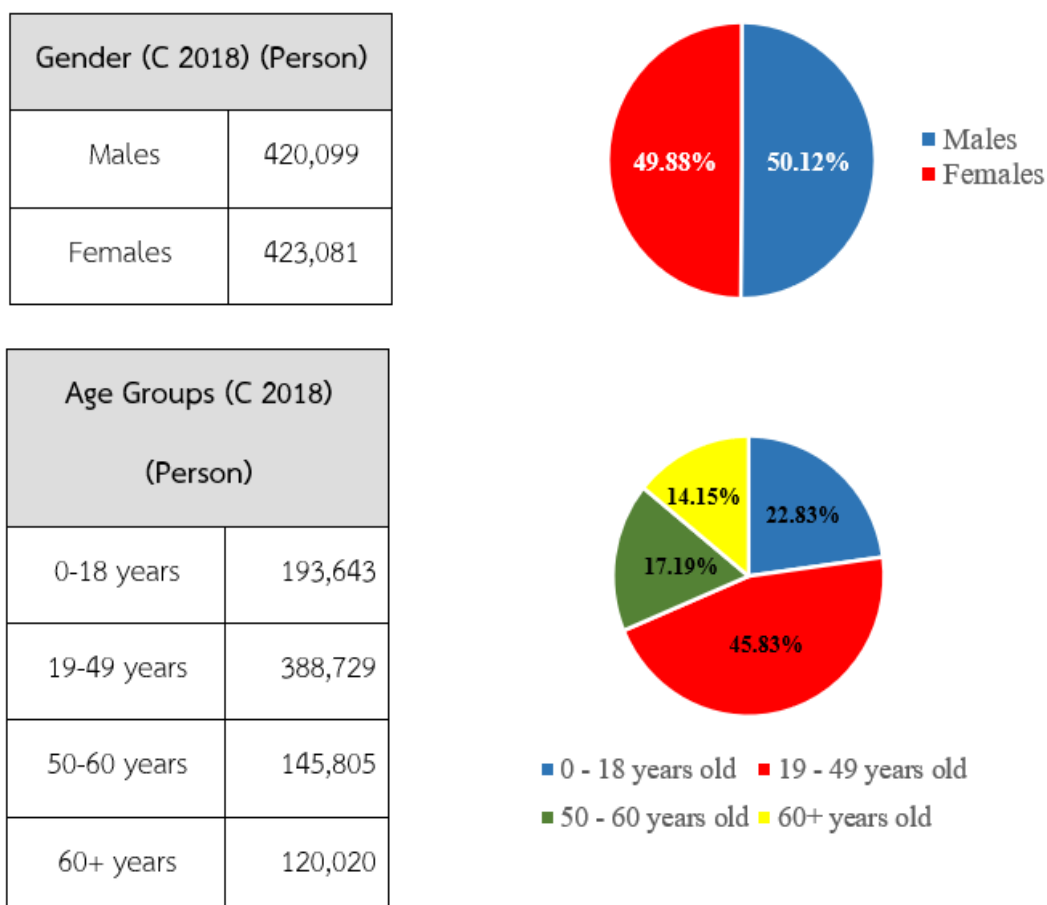

Fig. 3.2. Information about the population structure in Kanchanaburi province

3.1.2. Topography

The terrain of Kanchanaburi province has a very diverse and hierarchical structure. The topography of Kanchanaburi province gradually rises from the East to the West. There are three kinds of terrain in Kanchanaburi: mountains, valleys, and river basins. The mountainous topography is allocated in the North and West of province (in Sangkhla Buri, Thong Pha Phum, Si Sawat, some parts of Sai Yok, Bo Phloi, and Mueang Kanchanaburi districts) with an elevation ranging from 300 to 1800

meters, occupy three-fifths of total land area. The mountainous regions are mainly enveloped by natural and production forests with plant biodiversity.

The valleys area is located in the northeast of the province (in Lao Khwan, Phanom Thuan District, Bo Phloi, and Mueang Kanchanaburi districts) and comprises 20% of the total area. The characteristic of topographic structures is a hillside plain with low hills and groves, and slope direction is from east to southeast, mostly between 30 and 100 meters above sea level. The remaining area is the river basin, mainly located in the south and east of Kanchanaburi province (in Tha Muang, Tha Maka, and some parts of Phanom Thuan districts).

Fig. 3.3. Terrain of Kanchanaburi province in Thailand

3.1.3. Meteorological condition

The atmospheric circulation of Southeast Asian monsoons impacts the climate in

Kanchanaburi. It is the interconversion of climatic characteristics of the mountain and plain Thailand. The northeast monsoon often occurs between November and March; the southwest monsoon usually begins between May and September. The transition period is April and October. The province has two main seasons: summer and winter. In the dry season, the heat lasts a long time; conversely, cold spells occasionally appear in the wet duration. On the report of the Kanchanaburi people's committee about climate, weather features of the province are characterized as follows:

Temperature of the province is very high. It is approximately 38.2°C in the summer and around 31.3°C in the winter. The amplitude of temperature oscillates quite widely. April has the highest monthly mean temperature at approximately 38.2°C, and December is the lowest monthly mean one at just under 19.6°C (<https://www.weather-atlas.com>).

Fig. 3.4. Monthly temperature in Kanchanaburi province (2020)

The annual average relative humidity fluctuates from 61% to 80%. October typically occurs the highest humidity at 80%, and March usually has the lowest humidity at about 61%.

Fig. 3.5. Monthly humidity in Kanchanaburi province (2020)

The annual average precipitation is 1056.4 mm, but it does not distribute evenly in the province. The heavy rainfall is concentrated in mountainous areas. Between May and October, precipitation occupies around 83% of the annual rainfall total. The rest of the rainfall happens from November to April. September is the highest average rainfall of 220.5 mm, while January is the lowest with 3.3 mm.

Fig. 3.6. Monthly average precipitation and rainfall days in Kanchanaburi province (2020)

The annual average sunshine and daylight hours are approximately 31,700 hours

and 53,000 hours, respectively. The highest hours of sunshine happen from January to April and December; the average hours of sunshine in these months are around 9 hours per day. Moreover, the lowest hours of sunshine appear from July to September; the average hours of sunshine in these months are approximately 5 hours per day. June and July have the longest days, with 12.9 hours per day; meanwhile, December has the shortest day, with 11.3 hours per day.

Fig. 3.7. Monthly average sunshine and daylight hours in Kanchanaburi province (2020)

The Southeast monsoon's wind regime begins to blow into the Gulf of Thailand in late May and early June. The southeast monsoon blows through, causing more rain in the period from August to September. In winter, the northeast monsoon blows from the high-pressure area from China. The northeast monsoon is cold and dry. It blows over the whole of Kanchanaburi from October to February next year. The Northeast Monsoon begins to weaken in February, when the East Wind from the South China Sea and the Southeast from the Gulf of Thailand will take its place. In addition to the monsoons mentioned above, the area has occasional storms.

Climate change affects many weather elements such as the number of precipitations, temperature, sunshine duration, etc. Therefore, it impacts the groundwater

quality and quantity in Kanchanaburi. However, the effect of climate on groundwater takes a bit long time (for example, 50 years). According to [Srisuk et al. \(2016\)](#), climate change has degraded groundwater quality in coastal and inland areas in Thailand, such as saline water intrusion. While the analysis by [Pholkern et al. \(2018\)](#) indicated that groundwater resources in Central Huai Luang Basin are at risk due to climate change.

3.1.4. Hydrologic condition

Fig. 3.8. River systems and waterbody in Kanchanaburi province

Four river systems pass the Kanchanaburi province's territory, namely Khwae Noi, Khwae Yai, Mae Klong, and Lam Taphoen rivers. These rivers originate from the Khwae Noi river systems in Thong Pha Phum district and Thong Pha Phum district. Khwae Noi converges with Khwae Yai to form Mae Klong river in Pak Phraek ward, Mueang Kanchanaburi districts. Lam Taphoen river flows through the Eastern Plain of Kanchanaburi province and meets the Khwae Yai River at Tha Sao in Sai Yok district.

3.1.5. Soil resources

Kanchanaburi province has suitable soil conditions for cultivating crops such as sugarcane, maize, cassava, and pineapple. According to the survey of the land development department of Thailand (2007), the soil condition in Kanchanaburi is mainly formed from sedimentary rock by decomposition of igneous rock, granite, granodiorite, shale, and quartz phyllite. There are 33 soil group types found in Kanchanaburi province. Soil group 62 occupies 10,334.81 km², followed by soil group 33 (1029.55 km²), and soil group 29 (994.26 km²). Soil groups 31 and 48 have a total area of 935.54 km² and 841.98 km², respectively.

+ Soil group 62: This type of soil covers mainly hilly areas. It appears at places with a slope of more than 35%. The characteristic is deep and shallow. Soil texture and fertility vary according to the original rock, such as crushed stone, lump rock, or slate. This type of soil should not be used for agricultural purposes because of ecosystem conservation.

+ Soil group 33: Soil texture has brown or reddish-brown. It lies deep in the soil, contains mica or lime, is formed from sediment materials, and is found along rivers, hills, and mountains. This soil type usually appears in regions with a slope of about 2-12%. It has drainage from good to moderate; therefore, the groundwater level is more profound than 1m all year round. The soil group has moderate natural fertility. The topsoil layer has a pH in the range of 6.5-7.5.

+ Soil group 29: Soil texture is clay and delicate, with yellowish-brown or reddish colors. It originates from river sediments or degraded soils. This group is found in hills. It appears in areas with a slope of about 3-25%. It is deep and well-drained soil. Natural fertility is relatively low; the pH of soil ranges around 4.5-5.5. This type of land is currently used to grow different types of rice, crops, and fruit trees.

+ Soil group 31: Soil texture is clay. The feature is fertile. It has brown, yellow, and red colors due to the decomposition of many types of rocks. It is found in undulating and deformed regions. This group appears in regions with a slope of about 3-20%. This type of soil is deep and medium well-drained soil. The groundwater level is usually more than 1m deep. The natural average pH is 5.5-6.5. Currently, this type of soil is used to grow rice and various fruit trees.

+ Soil group 7: Soil texture is clay, has brown or gray-brown colors, and is formed by river alluvium. It is deep soil and poorly drained. It is found in flat and relatively smooth areas. The water level is 30-50 cm deep in the rainy season for 3-4 months. This group has naturally fertile and moderate fertility features. The pH ranges from 6.0-7.0.

3.1.6. Geological condition

Kanchanaburi is Thailand's westernmost province. It has a lot of high mountain ranges. The research study's geology consists mainly of metamorphic, igneous, and sedimentary rocks ranging in age from Precambrian to Quaternary. [Fig 3.9](#) depicts the geology in Kanchanaburi province.

Fig. 3.9. The geological map of Kanchanaburi province

3.1.6.1. Geological structure

The research area's structures are complex with folds and faults. The folds may be seen in various spots in Kanchanaburi from both field and satellite imagery (Songmuang et al., 2007). Most fold axes are in the northwest-southeast direction (Bunopas, 1976). Fold structures may be seen in a variety of rocks. It could be anticlinal and synclinal folds. The anticlinal and synclinal folds have been observed in the Ordovician and Permian limestones in the Khao Leam region. According to (Songmuang et al., 2007), tight and recumbent folds may be found in Ordovician to Devonian strata, mainly in the western section of Kanchanaburi city and the Three Pagoda Fault.

Many faults appear in western Thailand grouped into the Sri Sawat Fault and the Three Pagoda Fault (Chuaviroj, 1991; Pailoplee et al., 2009). The Sri Sawat Fault, which runs north-south, has a curved pattern with multiple smaller fault sets at its

southern end. The Sri Sawat Faults begin in Kanchanaburi Province's Sri Sawat district and the northern section of Bo Ploi district. In a northwesterly direction, this fault also flows through the Khwae Yai River. The Three Pagoda Fault deviates from the Mae-Ping Fault to the north, cutting Paleozoic to Cenozoic lithological units. Fig. 3.10 displays the active faults in Kanchanaburi province.

Fig. 3.10. The faults pass through Kanchanaburi province

3.1.6.2. Geological Setting

Kanchanaburi's geology comprises several faults that run in different directions, primarily northwest-southeast. These faults cut through various lithologies. The youngest unit consists of narrow and long strips of Quaternary deposits filled with laterites, silts, sands, and gravels. The Triassic rocks of the Chong Khab formation lie unconformably under the Quaternary layers. The *Daonella* sp, *Halobia* sp and sandstone interbedded with limestone make up the Chong Khab formation. The Permian Tha Madua sandstone,

which includes heavily bedded red sandstone and white quartz sandstone, underpins the Chong Khab formation. The Sai Yok Limestone is almost equivalent in age to the Tha Madua sandstone. This Permian-aged deposit consists of massive and bedded limestones with fusulinids, brachiopods, pelecypods, and bryozoans. The PermoCarboniferous-aged Khaeng Krachan formation underlies the Permian-aged Sai Yok formation. The Bo Ploi and Kanchanaburi formations, which are Silurian to Devonian in age, comprise pebbly mudstone, gray sandstone, and dark-gray shale. The Thung Song includes banded argillaceous limestone, argillite, and quartzite with Ordovician cephalopods is older than the Silurian-Devonian rocks. The Tarutao (or Chao Nen Group) of the Cambrian age is the earliest lithologic unit in the study area (Songmuang et al., 2007).

3.1.7. Hydrogeological characteristics

Groundwater sources in Kanchanaburi provinces can be divided into two main groups: Unconsolidated aquifers and Consolidated aquifer.

- Unconsolidated aquifers: Groundwater in unconsolidated rocks differ in both quality and quantity, depending on the type of sediment, biological characteristics, and structural characteristics of sediment accumulation. The areas in the South and East of Kanchanaburi are low-lying areas with a source of groundwater that can be utilized. Groundwater can be withdrawn to use at a rate of 30-50 m³/hour.

- Consolidated aquifer: Groundwater is stored in fractured materials such as granite, basalt, and limestone. The Western part of the Kanchanaburi province is mainly metamorphic rocks. Therefore, groundwater is shallow, less than 2 m³/hour (Sangkhla Buri, Sai Yok, Si Sawat, and Bo Ploi districts). Meanwhile, in places with low terrain (Mueang Kanchanaburi, Sai Yok, and Thong Pha Phum districts), the groundwater supplies above the threshold of more than 50 m³/hour.

In addition to limited groundwater resources, groundwater quality is another

issue in the study area. The total mass of matter is considered the overall chemical characteristics of groundwater. Total dissolved solid (TDS) is a term that uses to describe the total concentration of dissolved materials in water. The optimal value of total dissolved solids (TDS) is 600 mg/l and the maximum allowed is 1,200 mg/l.

TDS in groundwater in Si Sawat, Thong Pha Phum, and Sangkhla Buri districts was less than 500 mg/L. Meanwhile, TDS in groundwater in Sai Yok, Thong Pha Phum, Lao Khwan, and Bo Phloi districts was around 500-1,500 mg/l.

3.2. Research data

3.2.1. Data about groundwater yield assessment

3.2.1.1. Groundwater yield

Our case study considered eight site-specific variables, including altitude, distance to faults, distance to waterbodies, slope, geology, land use, rainfall, and soil type (Fig. 3.11). In previous studies, these variables were considered to influence groundwater yield and distribution (Abd Manap et al., 2014; Arulbalaji et al., 2019; Mumtaz et al., 2019; Naghibi et al., 2017a; Razandi et al., 2015). This study mostly obtained well-processed data from government agencies or, in some cases, extracted data from satellites using well-defined procedures to make our analysis workflow consistent for future studies (Diaz-Alcaide and Martínez-Santos, 2019). In particular, the altitude and slope layers were calculated based on the Aster Global Digital Elevation Model V003 from the National Aeronautics and Space Administration (NASA; <https://search.earthdata.nasa.gov>) using ArcGIS pro 2.8 (Khal et al., 2020). Land use and soil type maps were obtained from the Thailand Department of Agriculture. Global satellite precipitation data (CHRS, <http://chrs.web.uci.e.du>) were collected from the rainfall database to estimate the annual precipitation in Kanchanaburi Province during the time period between 2010 and 2020. The distance to waterbodies was digitized and calculated from Thailand's hydrological system. Geological and fault data were

collected from the Department of Mineral Resources. All spatial input layers were resampled to a 30 m resolution for the overlay analysis. Because the AHP and FR methods require categorical input variables for the analysis, the continuous variables in our study (that is, altitude, distance to faults, distance to waterbodies, slope, and rainfall) were classified into subclasses using the equal interval method.

3.2.1.2. Ground truth data

Our case study used groundwater yield as the ground truth data for GWP model training and map validation. Groundwater yield was collected from 1,601 wells across Kanchanaburi Province in a previous project funded by the Thailand Department of Groundwater Resources (DGR). The groundwater yield for 1,601 wells was partitioned based on the threshold of 10 m³/h into two datasets: those of wells with a groundwater yield of >10 m³/h and those of wells with a groundwater yield ≤10 m³/h (Fig. 3.11). Both datasets were used to train and validate the RF model, whereas only the dataset with a groundwater yield of >10 m³/h was used in the AHP and FR model training. The datasets were split into two subsets using a ratio of 70:30 for model training and validation, respectively. The detailed experimental designs for individual model buildings are presented in Section 3.3.1.

3.2.2. Data about heavy metal contamination risk assessment in groundwater

3.2.2.1. Ni contamination in groundwater

Ni contamination in groundwater is a phenomenon in which the Ni concentration exceeds the permissible level. According to Thailand's groundwater quality standards, Ni concentration in groundwater must not be more than 20 $\mu\text{g/L}$. For our case study, Ni data of 180 groundwater samples were collected from April to July 2021 and analyzed at Thailand Department of Groundwater Resources (DGR). The groundwater sample locations were displayed using the UTM coordinate system (Fig. 3.12). The concentration of Ni was measured in the laboratory by Atomic Absorption Spectrophotometry-Direct Aspiration method with a detection limit of 10 $\mu\text{g/L}$. Ni concentration in groundwater samples fluctuates from 10 to 72 $\mu\text{g/L}$ (Fig. 3.13). In 180 groundwater samples, 16 groundwater samples were contaminated with Ni.

Fig. 3.12. Positions of groundwater samples in study area

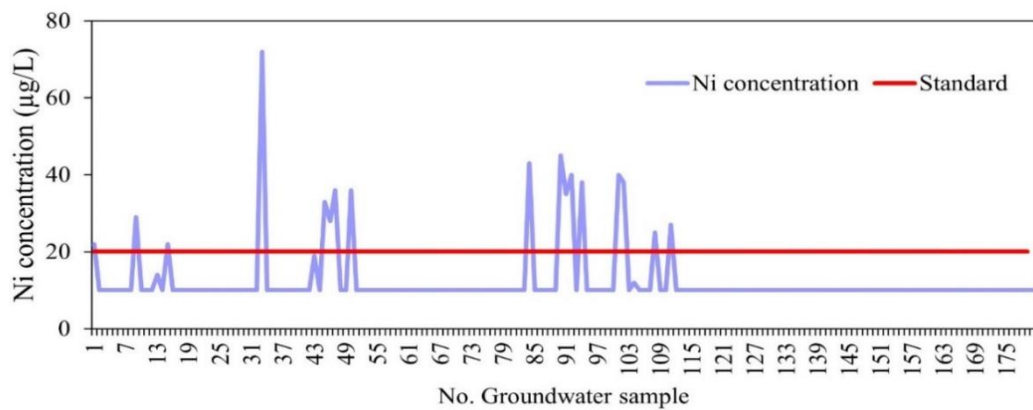

Fig. 3.13. Classification of Ni contaminated and uncontaminated groundwater samples

3.2.2.2. Influencing factors

The groundwater could be contaminated with Ni from anthropogenic and natural sources. Based on the previous surveys (Baumann et al., 2006; Mohankumar

et al., 2016; Sajedi-Hosseini et al., 2018; Twarakavi and Kaluarachchi, 2005; Uliasz-Misiak et al., 2022), eight environmental variables, including altitude, distance to roads, distance to waterbodies, geology, land use, rainfall, slope, and soil type were selected. In this study, all these factors were utilized as influencing factors to control the Ni contamination in groundwater. Maps of altitude and slope were extracted from the Aster Global Digital Elevation Model V003 satellite image. Distance to roads and distance to waterbodies were processed and estimated by the “Euclidean Distance” function in the ArcGIS environment from Thailand's national database of hydrology and transportation, respectively. Geology and soil type maps were provided by the Thailand Department of Mineral Resources. Land-use map was collected from Kanchanaburi Provincial Land Office. A rainfall map was created from Global satellite precipitation data (CHRS, <http://chrs.web.uci.edu>). All influencing factors were prepared in raster format, with each pixel size of 30m x 30m.

3.2.3. Data about groundwater quality assessment

This study investigated previous publications relevant to groundwater quality assessment in reputable journals (Agrawal et al., 2021; Amiri et al., 2014; Asadi et al., 2019; Boateng et al., 2016; Chotpantararat and Thamrongsrisakul, 2021; Gulgundi and Shetty, 2018; Jha et al., 2020; Kawo and Karuppanan, 2018; Li et al., 2018; Rabei, 2018; Sadat-Noori et al., 2014; Sridharan and Senthil Nathan, 2017; Wali et al., 2019) (Supplementary Table S1). It was clear that the number of parameters was used differently in these studies. An investigation was then conducted statistics on the popularity of the parameters to select groundwater parameters with the use of above 50% for this study. Finally, potassium (K^+), sodium (Na^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), sulfate (SO_4^{2-}), bicarbonate (HCO_3^-), nitrate (NO_3^-), pH, electric conductivity (EC), total dissolved solids (TDS) and total hardness (TH) were selected to assess the groundwater quality in Kanchanaburi, Thailand.

Next, I inherited groundwater samples of 116 wells in Nong Prue, Bo Phloi, Mueang Kanchanaburi, and Dam Makham Tia districts from the Groundwater Resource Department (DGR) conducted from January to April 2022 and then collected 64 groundwater samples in Lao Khwan, Huai Krachao, Phanom Thuan, Tha Maka, Tha Muang districts in May 2022 to assure the coverage rate (Fig. 3.12). A total of 180 groundwater samples were used in this study (Supplementary Table S2). All groundwater samples were contained in 500-ml polyethylene bottles and labeled corresponding to information of each well after getting from the groundwater wells. The measurements of EC and TDS were conducted by Hach 51800-10 sensION 5 Waterproof Conductivity Meter with an accuracy of $\pm 0.5\%$. pH was measured by HQ40d Portable Multi Meter with an accuracy of ± 0.01 . Analysis of K^+ and Na^+ Ca^{2+} , Mg^{2+} , Cl^- , SO_4^{2-} , HCO_3^- , NO_3^- , and TH were implemented at the DGR. All the physical parameters were measured in the field. The analysis results were checked with internal standards (Wisitthammassri et al., 2020) and with an ion charge balance error percentage of 0.3% (lower than 5%) (Li et al., 2018).

After getting information on groundwater samples from the DGR, the study conducted an analytical process by the SPSS software to determine the statistical values. In addition, the Piper Trilinear diagram was used to observe hydrogeochemical properties in groundwater using the Graph software (Ratchawang et al., 2022), and a correlation matrix was estimated using the "library(corrplot)" in the R environment to analyze the "Pearson" correlation between the groundwater parameters and the normalized EWQI (Cortadellas et al., 2017). Next, a geostatistical process was applied to develop the groundwater quality map. It was an important procedure because it could not collect all field data on the whole study area. In geostatistical analysis, the two typical interpolation methods are IDW and Kriging. The IDW is known as a deterministic method for unknown values based on the distance

weight between known values. Kriging is an interpolation technique that measures the unknown based on spatial statistics of known values (Jha et al., 2020). The IDW is used when data is a non-normal distribution. Meanwhile, Kriging is used when data is a normal distribution (Kerry and Oliver, 2007). For our case study, the normal distribution was determined by the Kolmogorov-Smirnov test. As a result, all data of groundwater parameters were non-normal distributions, so the IDW was applied to generate the groundwater parameter maps (Table 4.11).

3.3. Methodologies

3.3.1. Methodologies for mapping groundwater yield

3.3.1.1. Analytic Hierarchy Process (AHP)

AHP is a decision analysis technique based on the selection criteria of experts to evaluate a problem (Wang et al., 2009). Because of its effectiveness, it is applied to many fields of science and technology, including groundwater potential mapping (Arulbalaji et al., 2019; Das et al., 2019; Razandi et al., 2015). It provides quick support by examining the weight and condition factors of groundwater potential (Kumar and Krishna, 2018). The limitation of the AHP approach is the dependence on expert's knowledge and experience, which can lead to a few inconsistencies in some cases (Velasquez and Hester, 2013). In this study, five groundwater experts belonging to the DGR were asked to perform the AHP analysis. The experts were requested to provide ranking scores in the pairwise comparisons based on how they think a variable (influencing factor) or variable's subclass might be more important than the other for getting groundwater yield $>10 \text{ m}^3/\text{h}$. Then, the influencing factors were integrated according to Saaty's 1–9 scale based on the experts' evaluation (Saaty, 1990). The influencing factors were independently determined such that only the odd scores were used for the AHP technique. These scores were defined based on different levels: 1 - equal importance, 3 - somewhat more important, 5 - much more

important, 7 - very much more important, and 9 - absolutely more important. A pairwise comparison matrix was utilized to collate the hierarchy of variables in the next step (Table 4.1). Eventually, the weight of factors on outcomes was calculated using a diagonal matrix (Table 4.2). Equations (2) and (3) were utilized to test the consistency ratio of the AHP model (Saaty, 1990):

$$CI = \frac{\lambda_{max} - n}{n - 1} \quad (2)$$

$$CR = \frac{CI}{RI} \quad (3)$$

where CI is the consistency index, λ_{max} is the highest eigenvalue in the comparison pairs, n is the number of factors ($n = 8$), CR is the consistency ratio, and RI is the random consistency index. The RI value was detailed in the previous study (Alonso and Lamata, 2006). The AHP is accepted when CR is less than 0.1 (Malczewski, 1999). In this model, the groundwater potential index was calculated based on the weight of the influencing factors and Saaty's 1–9 scale of subclasses, which was formulated as per equation (4) (Al-Djazouli et al., 2021; Arulbalaji et al., 2019; Owolabi et al., 2020):

$$GWPI_{AHP} = \sum W_i R_j \quad (4)$$

where $GWPI_{AHP}$ is the groundwater potential index, W_i is the weight of the influencing factor i^{th} , and R_j is the Saaty's 1–9 scale of subclass j^{th} of influencing factor i^{th} assigned by experts. After achieving the $GWPI_{AHP}$, the study applied equation (5) to normalize this indicator into the scaling of 0 to 1.

$$X_{Normalized} = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (5)$$

where $X_{Normalized}$ is the normalized value, X is the original value, and X_{min} and X_{max} are the original minimum and maximum values.

3.2.1.2. Frequency Ratio (FR)

FR, a statistical algorithm, is used to calculate the probability of a particular object or phenomenon (Bonham-Carter, 1994). The FR model was employed to determine the possibility of groundwater occurrence with a particular yield in a basin in a previous study (Guru et al., 2017). Influencing factors were considered independent variables, while groundwater yield was regarded as a dependent variable (Razandi et al., 2015). The advantage of the FR technique is that the output weights of conditional factors are based on statistical data. The drawback of RF is its dependence on the ground truth data and method to classify subclasses of influencing factors (Wang et al., 2020). For our case study, the FR model was deployed based on the dataset of wells with a groundwater yield $>10 \text{ m}^3/\text{h}$ and the number of pixels of each variable's subclass to calculate the groundwater potential index. The equations for the FR approach were expressed as follows. Firstly, the FR value of each class was calculated by equation (6):

$$FR = \frac{\left(\frac{E}{TE}\right)}{\left(\frac{F}{TF}\right)} \quad (6)$$

where FR is the probability of occurrence of groundwater yield $>10 \text{ m}^3/\text{h}$ on each subclass of influencing factor, E is the number of well locations with groundwater yield $>10 \text{ m}^3/\text{h}$ involving each subclass of influencing factor, TE is the total number of well locations, F is the number of pixels in each subclass of influencing factor, and TF is the total number of pixels of influencing factor. Secondly, the relative frequency (RF_{FR}) was calculated as follows:

$$RF_{FRi} = \frac{FR_{ij}}{\sum FR_j} \quad (7)$$

where RF_{FRi} is the relative frequency of the i^{th} subclass of j^{th} influencing factors (j ranges from 1 to 8). FR_i is the frequency ratio value of i^{th} subclass. $\sum FR_j$ is the total frequency ratio value of j^{th} influencing factors. Next step, the predicted value (PV) was calculated by equation (8):

$$PV_j = \frac{RF_{FRij_max} - RF_{FRij_min}}{(RF_{FRij_max} - RF_{FRij_min})_{average}} \quad (8)$$

where RF_{FRij_max} is the maximum RF_{FR} value of j^{th} influencing factors, RF_{FRij_min} is the minimum RF_{FR} value of j^{th} influencing factors. The calculated values (RF & FV) were used to determine a set of many pixels with a groundwater potential index (GWPI) by equation (9):

$$GWPI_{FR \text{ model}} = \sum(RF_{FRi} \times PV_j) \quad (9)$$

Similar to the AHP, the $GWPI_{FR \text{ model}}$ was normalized into a scale of 0 to 1 using equation (5).

3.3.1.3. Random Forest (RF)

RF is an assembly algorithm for classification or regression based on multiple decision trees in a predictive model (Breiman, 2001). The tree's branches are formed from attributes of variables. The number of variables and decision trees must be determined before a model is implemented (Liaw and Wiener, 2002). In the GWP research, the RF model has been applied to define the potential location and reserves of groundwater based on well data and influencing factors (Naghibi et al., 2017a; Rahmati and Melesse, 2016; Zabihi et al., 2016). The training data for the RF models are encoded in a binary tree algorithm, which generates the nodes in a decision tree. The prediction error is estimated and influencing variables are permuted (Catani et al., 2013). However, the RF model overfits when training datasets are small or when there are too many input features (Wang et al., 2020). In our case study, an RF model was created to classify groundwater yield into two classes of yield below (class 0) and above (class 1) $10 \text{ m}^3/\text{h}$ based on the eight input influencing factors. Because the groundwater yield data was imbalanced, stratified random sampling was used to create the training and testing data for the RF model building. The groundwater yield data for 1,601 wells was first split into two strata using the groundwater yield threshold of $10 \text{ m}^3/\text{h}$. The individual strata were then

randomly split into two subsets using a ratio of 70:30 before being combined into a training and testing set, respectively. This ensures that enough data from the two classes is available in both the training and testing sets for proper model training. The Caret package in the R program (Naghibi et al., 2017a) was used to train and tune the binary RF classifier. Ten-fold cross-validation was used to reduce overfitting on the training set during model training. Categorical input influencing factors, including geology, land use, and soil type, were converted into one-hot encoding (Nguyen et al., 2020a) depending on which method provides a better accuracy score. The cutoff threshold of prediction probability for class 1 (that is, groundwater yield $>10 \text{ m}^3/\text{h}$) was set using the optimal value (optimal threshold) of the model in this study. The Gini importance (Kalantar et al., 2019) derived from the RF model training was used to rank the importance of the input variables (nominal weights) in classifying the groundwater yield. Regarding the calculation of the groundwater potential index, the study used the prediction probability from the RF model to generate the GWPZ map. Because probability below the optimal threshold was associated with groundwater yield of $<10 \text{ m}^3/\text{h}$, the study used the optimal threshold value which was the minimum probability of the groundwater yield above the $10 \text{ m}^3/\text{h}$ class. The adjusted probability dataset was then scaled between 0 and 1 using min-max normalization and used as the GWPI for the RF model.

3.3.1.4. Ensemble model

Ensemble refers to the combination of multiple alternative models to obtain better predictive performance than that obtained from individual ones (Opitz and Maclin, 1999). Since these alternative models are often trained using different algorithms or different datasets, they tend to cancel each other's weaknesses out and improve the overall accuracy (Muavhi et al., 2021; Rajaei et al., 2019; Yan et al., 2019).

In this study, to create an ensemble model of AHP, FR, and RF for GWP mapping, the study averaged the GWPIs from the three individual models. These GWPIs have been normalized to be on the same scale (0-1) in previous models.

3.3.1.5. Mapping of groundwater potential zones

For visualization purposes and better decision-making, the normalized GWPI was delineated for potential zones with groundwater yields above 10 m³/h using Jenk's natural break function in the ArcGIS environment (Kumar et al., 2016). The potential zones were classified into three levels, high, moderate, and poor.

3.3.1.6. Validation for maps of groundwater potential zones

The validation of a model is essential for determining its predictive power (Chen et al., 2019c). The Receiver Operating Characteristic (ROC) curves and the Area Under the Curve (AUC) metrics (Naghibi et al., 2017a) were used to compare the performance of the three GWP models in this study. The ROC curves were obtained by plotting the cumulative area of GWPI zones represented by the validation wells on the y axis against (1 – GWPI) on the x axis (Fig. 3.14). The AUC, the area limited by the ROC space, demonstrates the accuracy of a prediction system by describing the system's ability to accurately predict the occurrence or non-occurrence of pre-defined "events" (Jothibas and Anbazhagan, 2016). The AUC value ranges from 0 to 1. For our case study, a perfect GWP model should have all validation wells fall into zones with a GWPI of 1 (or a 1-GWPI value of 0), corresponding to the AUC of 1. This is because validation wells have a groundwater yield above 10 m³/h, and therefore their probability, or "potential", is always 1. However, perfect GWP models are unlikely to exist. A good predictive GWP model aims to cover most of the validation wells in the high GWPI zones (that is, zones with low 1- GWPI). In other words, the closer the AUC value is to 1, the better the GWP model is.

To construct a ROC curve, the study classified the corresponding GWPI map

into 100 classes (incremented by 0.01 unit). Validation wells were also plotted on the classified map and the area of the GWPI zones that have the validation wells was recorded. The area of GWPI zones was normalized between zero and one by dividing its raw value by the total area represented by all validation wells. The GWPI and the corresponding zonal area represented by the validation wells were sorted in descending order of the GWPI. The cumulative area was then calculated by adding a value to the previous one in the sequence.

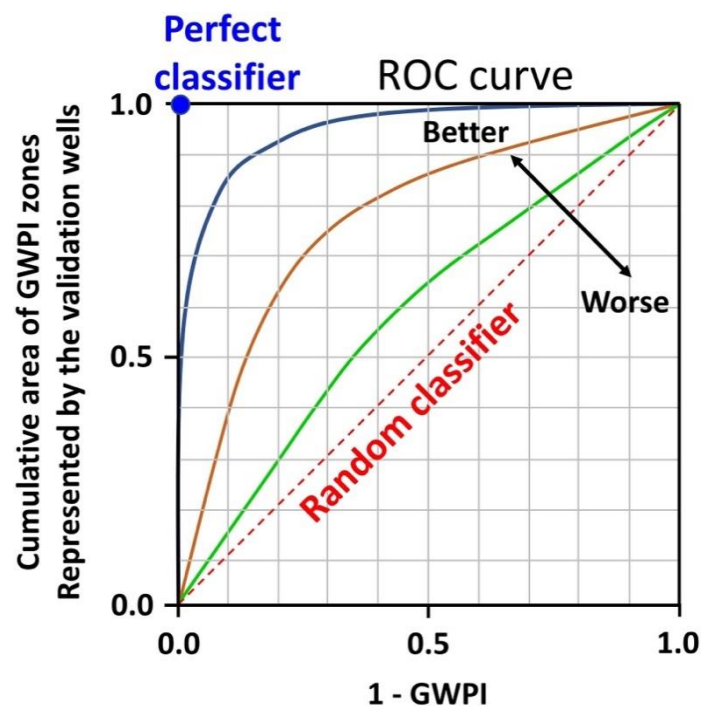

Fig. 3.14. Receiver Operating Characteristic curves and Area Under the Curve metrics

3.3.2. Methodologies for mapping Ni contamination risk zone in groundwater

The research process was carried out the following steps (Fig. 3.15): Step one is to build a database for the model. The input data includes the position of boreholes, information about influencing factors, and classification of Ni contamination and non-contamination. Groundwater samples are classified into contaminated and uncontaminated based on the Thailand groundwater quality standard for drinking purposes and were coded as 0 and 1. 0 is the uncontaminated

sample, and 1 is the contaminated well by Ni element. The database is divided into a ratio of 70:30 to train the model and test the results (126 samples for training; 54 samples for validating). Step two sets the weighted criteria and ranks the influencing factors based on contribution level and predicted value based on the Maxent technique, respectively. Step three calculates the AHP weight of influencing factors on the Ni contamination in groundwater using the AHP technique. Step 4 maps the Ni contamination risk zones in groundwater in the study area. Step 5 is validation.

Fig 3.15. Flowchart for delineating the Ni contamination risk zones in groundwater

3.3.2.1. Maxent

Maxent is a statistical technique based on the maximal distribution of known outcomes (Mousazade et al., 2019). In this technique, the probability distribution function is built based on environment variables. The prediction result uses the probability distribution function to calculate the phenomenon's occurrence probability (Reddy and Dávalos, 2003). However, the maxent technique works towards a uniform distribution without considering the constraints of the environment variables (Kaky et al.,

2020). In this study, Maxent was used to estimate the maximum occurrence probability of heavy metal pollution in the study area and the contribution level of environmental factors. The Maxent mathematical formulas are as follows (Mousazade et al., 2019):

$$P_{ij} = \frac{b}{a} \quad (10)$$

$$(P_{ij}) = \frac{P_{ij}}{\sum_{i=1}^{S_j} P_{ij}} \quad (11)$$

$$H_j = - \sum_{i=1}^{S_j} (P_{ij}) \log_2(P_{ij}) ; j = 1; 2; 3; \dots; n \quad (12)$$

$$H_{jmax} = \log_2 S_j \quad (13)$$

$$I_j = \frac{H_{jmax} - H_j}{H_{jmax}} \quad (14)$$

$$W_j = I_j P_{ij} \quad (15)$$

Where i is symbol for the i^{th} influencing factors (i ranges from 1 to 8), j is symbol for the j^{th} class of the influencing factors, a is the area of each class of each influencing factor, b is the number of contaminated groundwater samples in the j^{th} class of the i^{th} influencing factor, P_{ij} is the occurrence probability of Ni contamination in the j^{th} class of the i^{th} influencing factor, (P_{ij}) is the density probability, H is the entropy values, H_{jmax} is the maximum entropy value. The computing contribution level of influencing factors to the Ni contamination risk and the predicted value are performed in the R program environment with the SDM package (Algorithm 1).

Algorithm 1. Maxent approach

- 1: # Install package "SDM" and "Java environment"
 - 2: # Import databases
 - 3: # Construct maxent model
 - 4: MX = max('environmental factors', 'train data')
 - 5: # Getting the contribution variable
 - 6: plot(MX)
-

7: # Get the predicted value

8: response(MX)

3.3.2.2. Analytic Hierarchy Process (AHP)

AHP is a technique in making decisions. In the AHP technique, the weighted criteria of the conditional variables are usually determined based on experts' opinions on with scale of 1 to 9 (Saaty, 1990). The odd scores are defined according to different levels: 1 - equal importance, 3 - somewhat more important, 5 - much more important, 7 - very much more important, 9 - absolutely more important. Meanwhile, the even scores are defined as intermediate values when compromise is needed (Saaty, 1990). In this study, the influencing factors were determined independently so that the odd scores were only used to set the weight criteria for the AHP model. The weighted criteria of influencing factors and the ranks of their classes were assigned based on the contribution level and the predicted values from the Maxent method, respectively. For the weighted criteria, the contribution level was normalized by a common scale based on Eq. (16), and then applied as following principle: 0-0.2 was assigned 1, 0.2-0.4 was assigned 3, 0.4-0.6 was assigned 5, 0.6-0.8 was assigned 7, 0.8-1 was assigned 9. For the ranks of classes, the scores were given from 1-9 (only odd scores) based on the predicted values. The higher the predicted value was, the higher the score was, meaning that the probability of contamination occurrence is high. After the weighted criteria were set, calculating the AHP weights of the influencing factor were performed in a pairwise comparison matrix. In the AHP approach, the consistency ratio less than 0.1 was used to evaluate the matrix results (Arulbalaji et al., 2019; Saaty, 1990). The consistency ratio was estimated according to the Eqs. (17) and (18):

$$X_{normalized} = \frac{CL - CL_{minimum}}{CL_{maximum} - CL_{minimum}} \quad (16)$$

$$CI = \frac{\lambda_{max} - n}{n - 1} \quad (17)$$

$$CR = \frac{CI}{RI} \quad (18)$$

where $X_{normalized}$ is the normalized value of contribution level, CL is the value of contribution level of the i^{th} influencing factors, CI is the consistency index, n is the number of environmental factors, λ_{max} is the highest eigenvalue of pairwise comparison matrix, CR is consistency ratio, RI is the random index of the number of environment variables. The RI value is detailed in the study of (Alonso and Lamata, 2006).

3.3.2.3. Calculating potential contamination index and mapping the nickel contamination risk zones

The potential contamination index is a dimensionless quantity. In this study, the potential contamination index was used to predict groundwater's Ni contamination risk. Based on the previous studies about potential prediction (Achu et al., 2020; Adiat et al., 2012; Arulbalaji et al., 2019; Dar et al., 2021; Saranya et al., 2020), the potential contamination index of Ni in groundwater for each location was estimated according to the following formula:

$$GWPCI = \frac{Al_w Al_f + DtR_w DtR_f + DtW_w DtW_f + Geo_w Geo_f + LU_w LU_f + R_w R_f + SL_w SL_f + S_w S_f}{\sum w_f} \quad (19)$$

Where GWPCI is the potential contamination index of Ni in groundwater, Al is the altitude, DtR is the distance to roads, DtW is the distance to waterbodies, Geo is the geology, LU is the land use, R is the rainfall, SL is the slope, and S is the soil, w is the weight of influencing factor, f is rank of the classes of the influencing factor.

The potential contamination index map of Ni in groundwater was based on the value of pixels calculated from equation (19). The GWPCI values were classified into three different levels, including high, moderate, low, using the Natural Breaks function in ArcGIS software.

3.3.2.4. Validation for contamination risk map of Ni in groundwater

The results verification is an essential step in scientific and forecasting studies (Barzegar et al., 2018). In the current study, the data for validating the output map was based on 54 groundwater samples (30% database for testing). The receiver operating characteristic (ROC) and statistical indicators were proposed to evaluate the model's performance and accuracy of the output map (Tien Bui et al., 2019). The ROC is a graphical plot of a curve that represents the relationship between sensitivity and 1 – specificity or true positive rate and false positive rate (Pham et al., 2019). The ROC value is the area under the curve, namely the area under curve (AUC) (Tien Bui et al., 2019). The AUC value changes from 0 to 1. AUC value close to 1 means the high model's performance, and vice versa. The statistical indicators include positive predictive value (PPV), negative predictive value (NPV), accuracy, sensitivity, specificity. These statistics are calculated based on the equation (20, 21,22,23,24) and confusion matrix (Table 3.1) (Pham et al., 2019):

$$\text{Sensitivity} = \frac{TP}{TP+FN} \quad (20)$$

$$\text{Specificity} = \frac{TN}{TN+FP} \quad (21)$$

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \quad (22)$$

$$\text{PPV} = \frac{TP}{TP+FP} \quad (23)$$

$$\text{NPV} = \frac{TN}{TN+FN} \quad (24)$$

Where TP is the amount of pixels correctly classified as contamination samples (positive results), TN is the amount of pixels correctly classified as “non-contamination samples” (negative results), FP is the amount of pixels incorrectly classified as “contamination samples” (positive results), FN is the amount of pixels incorrectly classified as “contamination samples” (negative results).

Table 3.1. Matrix for observed and predicted values

		Result	
		Polluted samples	Non-polluted samples
Observation	Polluted samples	TP	FN
	Non-polluted samples	FP	TN

3.3.3. Methodologies for mapping groundwater quality

3.3.3.1. EWQI computation

Entropy is a technique to calculate objective quality parameter weights (Peiyue et al., 2010). It overcomes the weighting system's subjectivity. The entropy creates a network of information to assess the indirect connections of variables. The influenced weight of a variable is mainly determined by the difference of alternative values when using another variable. Data is less information when the entropy value is high, and therefore the result is more unpredictable. In the procedures of calculating the EWQI, each parameter is given an entropy weight (Wu et al., 2018). In this study, groundwater samples and physicochemical parameters are assigned in the order of i from 1 to 180 (i.e., 180 groundwater samples) and j from 1 to 12 (i.e., twelve parameters), respectively. Mathematically, the formulas for computing the EWQI are presented as follows:

$$A = \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1j} \\ a_{21} & a_{22} & \dots & a_{2j} \\ a_{i1} & a_{i2} & \dots & a_{ij} \end{bmatrix} \quad (25)$$

$$b_{ij} = \frac{x_{ij} - x_{ij \min}}{x_{ij \max} - x_{ij \min}} \quad (26)$$

$$B = \begin{bmatrix} b_{11} & b_{12} & \dots & b_{1j} \\ b_{21} & b_{22} & \dots & b_{2j} \\ \dots & \dots & \dots & \dots \\ b_{i1} & b_{i2} & \dots & b_{ij} \end{bmatrix} \quad (27)$$

$$P_{ij} = \frac{(1+b_{ij})}{\sum_{i=1}^m (1+b_{ij})} \quad (28)$$

$$e_j = -\frac{1}{\ln m} \sum_{i=1}^m P_{ij} \ln P_{ij} \quad (29)$$

$$w_j = \frac{(1-e_j)}{\sum_{i=1}^m (1-e_j)} \quad (30)$$

$$q_j = \frac{C_j}{S_j} \times 100 \quad (31)$$

$$EWQI = \sum_{j=1}^n w_j \times q_j \quad (32)$$

where A is the Eigenvalue matrix, b_{ij} is standardized value, B is a standard-grade matrix, P_{ij} is performance indices, e_j is the information entropy, w_j is the entropy weight, C_j is the concentration of parameters j , S_j is the permissible standard value, q_j is the quality rating scale. After achieving the EWQI, the study has applied equation (9) to normalize this indicator into the scaling of 0 to 1.

$$EWQI_{Normalized} = \frac{EWQI - EWQI_{min}}{EWQI_{max} - EWQI_{min}} \quad (33)$$

where $EWQI_{Normalized}$ is the normalized value, EWQI is the original value, $EWQI_{min}$ and $EWQI_{max}$ are the original minimum and maximum values. For visualization purposes and better decision making, the normalized EWQI was classified into five levels of groundwater quality, including excellent quality ($EWQI_{Normalized}$ of 0-0.2), good quality ($EWQI_{Normalized}$ of 0.2-0.4), moderate quality ($EWQI_{Normalized}$ of 0.4-0.6), poor quality ($EWQI_{Normalized}$ of 0.6-0.8), extremely poor quality ($EWQI_{Normalized}$ of 0.8-1).

3.3.3.2. Cross-validation and bootstrap techniques

In this study, the initial database, including 16 columns and 180 rows, was designed based on a matrix structure in which the columns were the information on the groundwater parameters and the rows were the information on groundwater

samples (Supplementary Table S2). In the initial database, groundwater parameters were the independent variables, the normalized EWQI was the target variable. Cross-validation and bootstrap techniques were then applied to build training and testing data subsets for the ML models. Cross-validation and bootstrap are resampling methods (Kohavi, 1995). While the cross-validation divides the initial dataset into multiple subsets for training and testing (Berrar, 2019), the bootstrap generates multiple subsets from the initial database after resampling with replacement (Chernick, 2012). For the cross-validation, the initial database was split into five subsets, each subset is called a data block (fold) comprised of 36 groundwater samples (Fig. 3.16a). For the bootstrap, the initial database was divided into 100 multiple subsets after resampling with replacement (Fig. 3.16b).

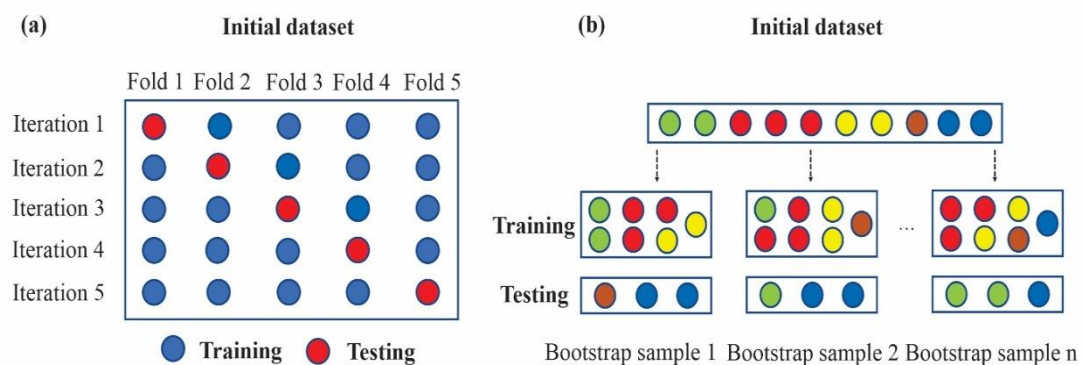

Fig. 3.16. Cross-validation (a) and bootstrap (b)

3.3.3.3. Random forest (RF)

Achievement in the application of the RF model has been recorded remarkably in branches of environmental science such as landslides (Cheng et al., 2021), floods (Schoppa et al., 2020), air pollution (Kumar, 2018), land use management (Wu et al., 2021), and water quality (Wang et al., 2021). The RF, an ensemble learning method, is established from the decision trees. In the RF model, a decision tree is an option for forecasting results, in which tree branches are a combination of data classes based on different datasets and attributes (Ahmad et al., 2017). An ensemble output of the RF is

an aggregate of the decision trees, therefore, the information on the decision trees complements each other, resulting in a model with low bias and low variance (Goldstein et al., 2011). As a corollary, the RF model solves overfitting and underfitting problems on the validation/test subset. An RF model conducts the task of classification or regression (Liaw and Wiener, 2002). In the RF algorithm, the number of decision trees (n-tree) and attribute information (m-try) must declare to determine the optimal model. However, the RF model returns results in a long time because it processes many predictions. For our case study, the RF algorithm was implemented in the R program environment using the “Caret” package. To start, the study built the control subjects using the "trainControl function" based on the cross-validation and bootstrap, respectively. Then, the study integrated the control subjects into the RF algorithm, called RF-CV and RF-B models, respectively. The role of RF in this study was to conduct a regression task because the normalized EWQI is a continuous variable ranging between 0 and 1. The value of the normalized EWQI for locations in the study area was conducted by the prediction function.

3.3.3.4. Artificial neural network (ANN)

The ANN, a machine learning model, is applied by many researchers to make predictions (Soltani Mohammadi et al., 2017; Tamiru and Dinka, 2021; Xu et al., 2021). The ANN is developed from a structure that is similar to the behavior of neurons and synapses in the human brain. It allows computer programs to recognize complex relationships in a dataset and solve the problem of prediction (Lee et al., 2017). The structure of an ANN model includes an input layer, hidden layers, and an output layer (Ahmad et al., 2017). The input layer represents input data, hidden layers represent the intermediate nodes that divide the input space into boundary regions, and the output layer represents the output of the neural network (Monteiro et al., 2021). Similar to the RF, the ANN can perform classification or regression missions. The ANN works based on the correlation of input data to make decisions. However,

ANN only works with numeric data and requires large datasets, which requires the categorical data need to be generalized coding (Tayyebi and Pijanowski, 2014). For our case study, the groundwater parameters were designated as the input layer, and the normalized EWQI was appointed as the output layer. The “neuralnet” package was performed directly in the R program. The cross-validation and bootstrap techniques were integrated into the ANN algorithm to build the ANN models, called the ANN-CV and ANN-B, respectively. The default number of hidden layers was one with a threshold of 0.05 because the more hidden layer is, the more complex the model is (Bedi et al., 2020). The ANN-CV and ANN-B algorithms were presented in supplementary materials.

3.3.3.5. Model validation

Modeling can lead to deviations between forecast and observed values. Therefore, model validation is an essential step for any model. For our case study, coefficient of determination (R^2), root mean square error (RMSE), and mean absolute error (MAE) were utilized to accurately validate and compare the performance between the models (Bedi et al., 2020). The R^2 is an indicator to explain the coefficient of variance explanation, which describes the relationship between a set of parameters on the target variable. The value of R^2 varies from zero to one. The R^2 goes to one, the model is good, and vice visa (Santhi et al., 2001). The RMSE, an error-index statistic, is used to compare the performance of models. The lower the RMSE is, the more reliable model is. Similar to RMSE, MAE is also applied to evaluate the models. The value of MAE goes to 0, which means that model is more suitable (Chai and Draxler, 2014).

$$R^2 = \frac{\sum_{i=1}^n (EWQI_n - \bar{EWQI}_n) * (EWQI_p - \bar{EWQI}_p)}{(\sum_{i=1}^n (EWQI_n - \bar{EWQI}_n)^2)^{0.5} * (\sum_{i=1}^n (EWQI_p - \bar{EWQI}_p)^2)^{0.5}} \quad (34)$$

$$MAE = \frac{\sum_{i=1}^n (EWQI_n - EWQI_p)}{n} \quad (35)$$

$$RMSE = \sqrt{\frac{1}{n} ((EWQI_n - EWQI_p)^2)} \quad (36)$$

where $EWQI_n$ is the estimated value of normalized EWQI, $EWQI_p$ is the predicted value of the normalized EWQI.

Chapter 4. RESULTS AND DISCUSSION

4.1. Exploring spatial distribution of groundwater yield in Kanchanaburi, Thailand using AHP, FR, and RF

4.1.1. Influencing factors on groundwater yield

Altitude: Altitude affects groundwater distribution as water often moves down the elevation gradient. Therefore, it is an indicator of groundwater potential (Chen et al., 2019c). In the study area, altitude values ranged from 2 m to 1,812 m and were divided into five subclasses: 2–50 (2,331 km²), 50–100 (2,278 km²); 100–150 (1,263 km²); 150–200 (2,150 km²); and >200m (11,368 km²) (Fig. 4.1a).

Distance to faults: Faults are hydraulic barriers hindering horizontal groundwater movement. Therefore, it is an important factor to invest groundwater yield (Naghibi and Pourghasemi, 2015). The distance to faults map of Kanchanaburi was generated with five subclasses: 0–10,000, 10,000–20,000, 20,000–30,000, 30,000–40,000, and >40,000 m, in turn accounting for an area of 14,384, 2,480, 1,601, 857, and 67 km², respectively (Fig. 4.1b).

Distance to waterbodies: Distance to waterbodies affects the infiltration of groundwater and the recharge capacity of an aquifer (Chen et al., 2019c). The distance to waterbodies map was classified into five subclasses: 0–2,000 (13,315 km²), 2,000–4,000 (3,956 km²), 4,000–6,000 (1,388 km²), 6,000–8,000 (489 km²), and >8,000 m (242 km²) (Fig. 4.1c).

Slope: Slope determines excess rainfall and runoff accumulation and thus influences the residence time of water on the surface and the ability of water to seep into the underground (Nguyen et al., 2020c). The slope in the study area was

classified into five subclasses: 0° – 3° (3,304 km²), 3° – 6° (3,820 km²), 6° – 10° (3,122 km²), 10° – 16° (3,070 km²), and $>16^{\circ}$ (6,073 km²) (Fig. 4.1d).

Geology: Geology is important for the distribution of groundwater. Indeed, good aquifers are often found on fractured rocks (limestone, basalts, conglomerates, sandstone) and unconsolidated sediments (sand, gravel), while poor aquifers are composed of igneous rocks (granite, shale) or sediments (mud, clay, slit) (MacDonald and Davies, 2000). In the study area, there are fourteen geological units, including Carboniferous-Permian (CPk), Devonian (D), Cambrian (E), Cambrian-Ordovician (EO), Jurassic (J), Cretaceous (Kgr), Ordovician (O), Pre-Cambrian (PE), Permian (Pr), Quaternary (Q), Silurian-Devonian (SD), Silurian-Devonian-Carboniferous (SDC), Tertiary (Tmm), Triassic (Tr) in which Q covers the highest area (5,474 km²), followed by SDC (3,180 km²), O (2,647 km²), Pr (2,430 km²), Tr (1,472 km²). Moreover, other geological units occupy a small area of Kanchanaburi (Fig. 4.1e).

Land use: Land use reveals the current state of the surface coating of a geographic feature, which has a close relationship with groundwater through residence time and the infiltration process of surface water. It represents soil moisture, surface roughness, movement and recharge capacity of groundwater (Sameen et al., 2019). In Kanchanaburi, the land use factor comprises five land cover units, reclassified into agricultural land (5,323 km²), miscellaneous land (454 km²), forest land (12,224 km²), urban and built-up land (557 km²), and waterbody (506 km²) (Fig. 4.1f). Forest is primarily distributed in the West; moreover, agricultural, miscellaneous, urban and built-up lands concentrate in the East.

Rainfall: Rainfall greatly influences the recharge of groundwater through surface input and subsurface infiltration (Khoshtinat et al., 2019). The rainfall map was divided into five subclasses as follows: $<1,500$ (8,091 km²), $1,500$ – $1,650$ (4,223 km²), $1,650$ – $1,800$ (5,051 km²), $1,800$ – $1,950$ (1,964 km²), and $>1,950$ mm/year (60 km²)

(Fig. 4.1g).

Soil type: Soil controls the infiltration and retention rate of water, which is decided by soil structure and texture (Martinez-Santos and Renard, 2020). In Kanchanaburi, there are fourteen soil types in which clayey sand is the dominant type, comprising ~11,189 km² of the total area, followed by sandy loam (2,759 km²) and clay loam (1,987 km²). The others cover only a small part of the area and are sparsely distributed in the province (Fig. 4.1h).

Fig. 4.1. Influencing factors include (a) altitude, (b) distance to faults, (c) distance to waterbodies, (d) slope, (e) geology, (f) land use, (g) rainfall, (h) soil type

4.1.2. Application of AHP for delineating groundwater potential zones

The AHP approach provides the weight of the influencing factors for the presence of wells with a groundwater yield above 10 m³/h. A pairwise comparison matrix of influencing factors determined by the judgment of experts in the groundwater field was used to calculate their diagonal matrix (Tables 4.1 and 4.2). The highest weight of 28.66% was found in altitude and distance to faults. It was followed by distance to water and slope at 14.40%. Meanwhile, the figures for geology, rainfall, and soil type were only 3.95%, and land use was the least impact factor with a weight of 2.03% (Tables 4.2 and 4.33). The consistency ratio was 0.055 (Table 4.2) revealing the reasonability of the pair-wise comparison process.

Table 4.1. Pairwise comparison matrix of influencing factors

AHP	Al	DF	DW	Slope	Geology	LU	Rainfall	Soil type	Weight criteria
Al	1	1	3	3	7	9	7	7	9

While the high groundwater potential zones were observed mainly in the East

of Kanchanaburi Province, the poor groundwater potential zones were found in the western area (Fig. 4.3a). Specifically, 59.88% and 22.23% of GWP were represented by poor and moderate potential, respectively, while high potential accounted for 17.89% (Fig. 4.4).

4.1.3. Application of FR for delineating groundwater potential zones

The occurrence probability of groundwater well locations with a yield >10 m^3/h on influencing factors and its spatial relationship with influencing factors was observed using the FR approach (Table 4.4, Fig. 4.3b). This spatial relationship was shown by the predicted value, which was considered an indicator for calculating the GWPI. The spatial relationship will be positive, average, and negative when the predicted values are >1 , 1 , and <1 , respectively (Lee and Pradhan, 2006). It is clear that the well location with a yield of >10 m^3/h and certain influencing factors, including distance to faults, distance to waterbodies, land use, and rainfall, had a positive spatial relationship. Meanwhile, a negative spatial relationship was observed between well location and altitude, slope, geology, and soil type. Besides, the relative frequency is also another important indicator of the impact of an influencing factor's subclasses on the occurrence of groundwater yield above 10 m^3/h (Muavhi et al., 2021). In the influencing factor of altitude, the subclasses with a low value had a high relative frequency and vice versa. The relative frequency value was higher when the distance was far from the faults. The influencing factors showed a sharp contrast with distance from waterbodies, slope, and rainfall. About geological units, the analysis of the FR approach indicated that the Quaternary had the highest value of relative frequency (0.41), followed by the Cambrian (0.21), and Silurian-Devonian (0.17). According to land-use type, urban and built-up land had the highest value of relative frequency (0.90) followed by agricultural land (0.07). Also, an assessment of soil type revealed that the largest relative frequency values of 0.28 and 0.20 were found in silt and silt loam, respectively. The majority of areas were affected by moderate (43.58%) and poor (30.92%) potential, while the remaining areas were correlated with high potential (25.50%) (Fig. 4.4).

Table 4.4. Frequency ratio values of the influencing factors

Influencing factors	Subclasses	No. of pixels	% of pixels	No. of wells	% of Well	FR	RF _{FR}	PVj
Altitude	2-50 m	2,590,578	12.023	94	32.53	2.71	0.48	0.87

Abbreviations: FR - Frequency ratio; RF_{Fi} - Relative frequency of i^{th} subclass; PV_j - Predicted value of j^{th} influencing factors

4.1.4. Application of RF for delineating groundwater potential zones

As previously suggested in section 2.3.3, the RF model was conducted by the binary regression algorithm. The importance of influencing factors was also observed

by the RF model (Fig. 4.2). The contribution level to groundwater well occurrences with a yield >10 m³/h of distance to waterbodies was the highest (22.00%), followed by the altitude factor (20.40%). Distance to faults, slope and soil type was the next in the contribution level with 16.87%, 15.90%, and 11.88%, respectively. The other factors were insignificant or had a low impact. The final GWP map from the RF approach is presented in Fig. 4.3c. The majority of regions had poor potential at 60.67% of the area, followed by the proportion of moderate potential (20.79 %). Meanwhile, only 18.54% of the area was defined by high GWP (Fig. 4.4).

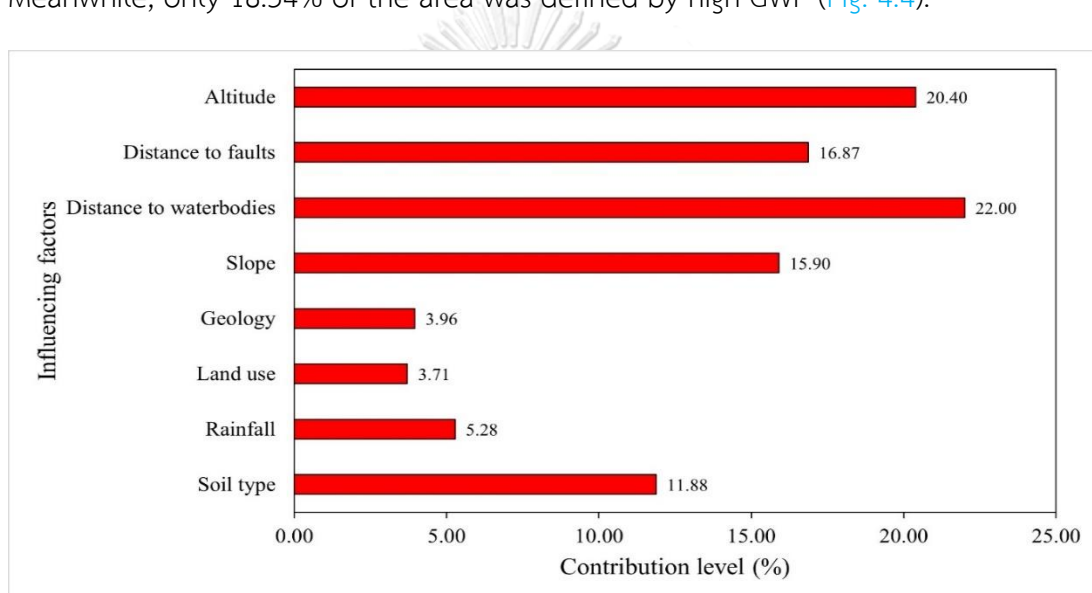

Fig. 4.2. Contribution level of influencing factors on groundwater yield >10 m³/h conducted by the RF

4.1.5. Application ensemble model of AHP, FR, RF for delineating groundwater potential zones

An ensemble model was created by averaging the normalized GWPIs predicted in this study by the AHP, FR, and RF models (Fig. 4.3d). Poor and moderate potential made up 36.42% and 30.15% of the area, respectively, while 33.43% of the area showed high potential (Fig. 4.4).

Fig. 4.3. Groundwater potential maps for yield >10 m³/h in Kanchanaburi Province, Thailand: (a) AHP model; (b) FR model; (c) RF model; (d) Ensemble model

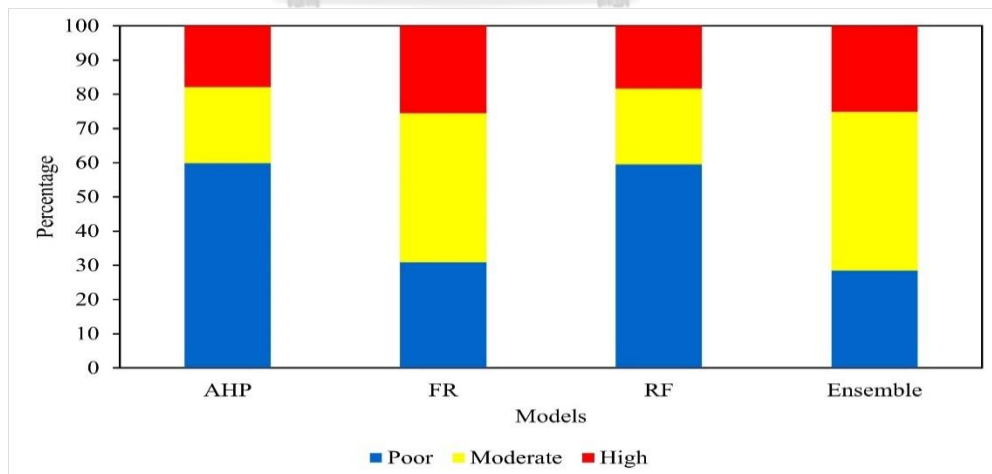

Fig 4.4. Area of GWP zones for groundwater yield >10 m³/h in Kanchanaburi Province

4.1.6. Assessment of the model's accuracy

The models' results were assessed by comparing the cumulative GPWIs of

the testing set via AUC value. The AUCs of the AHP, FR, RF, and ensemble models were 0.72, 0.74, 0.76, and 0.80, respectively (Fig. 4.5), revealing that all models achieved similarly good predictions. Nevertheless, individual models exhibited different behaviors. Specifically, the RF model did better at identifying the target groundwater yield at the GWPI above 0.6 (or 1-GWPI below 0.4) but worse at lower GWPI, compared to other models. The predictive power of FR was lower than that of the random classifier at the GWPI above 0.9 (that is, 1-GWPI below 0.1), but outweighed that of RF and AHP at the GWPI below 0.6. The AHP model, on the other hand, expressed monotonic behavior across the GWPI range. Combining the results from all models into an ensemble did improve the overall model prediction. The ensemble model achieved an AUC score of 0.8 and performed better for the GWPI values between 0.2 and 0.8, whereas all the individual models fell short.

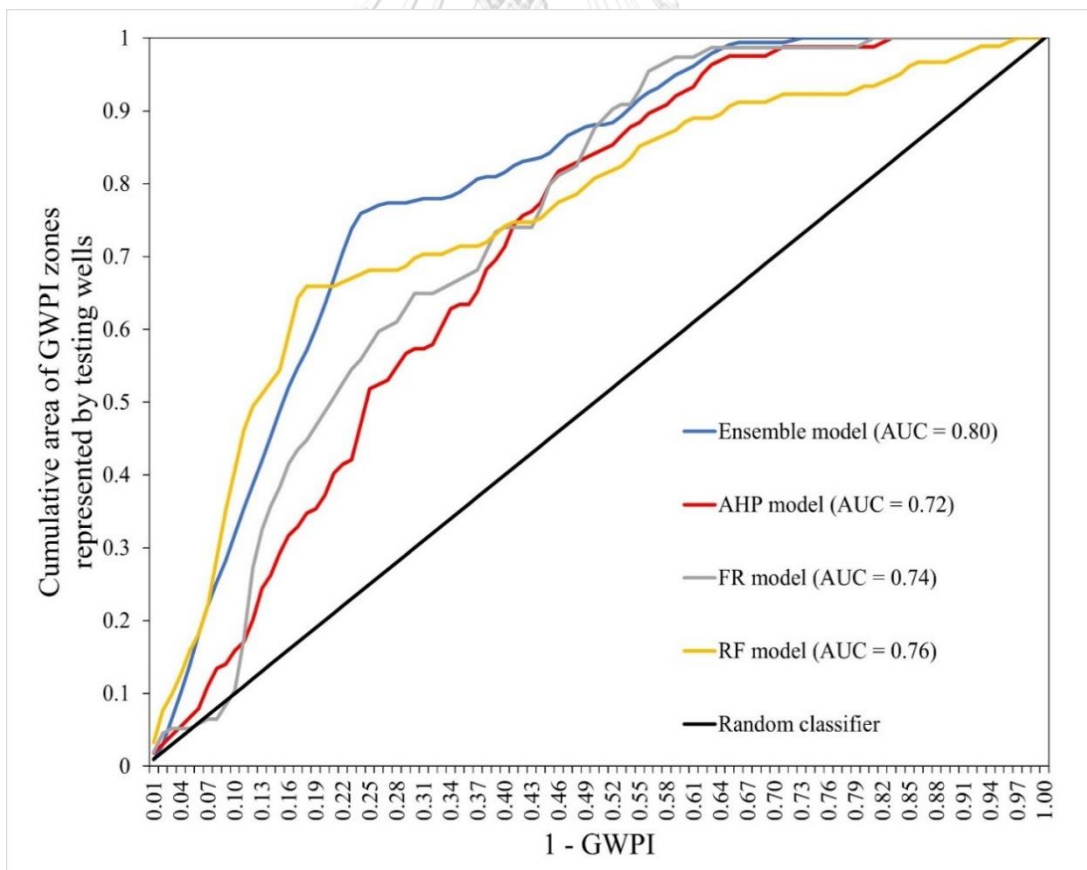

Fig. 4.5. Validation of models.

4.1.7. Discussion

Quantifying the importance of the influence factors on groundwater processes helps policy-makers improve water resource planning. In our study, the models used have different mechanisms to weigh the influencing factors as they belong to different approaches. The AHP model used a decision system approach, so the weights of influencing factors were assigned completely based on expert opinions and domain knowledge, while the FR and RF models assigned weights based on data analysis. The FR method eliminated human interference and simply assigned weights based on the number of wells with a groundwater yield exceeding $10 \text{ m}^3/\text{h}$ that fell into different sub-classes of the influencing factors. The RF, on the other hand, used more sophisticated optimization algorithms to compute the weight for each influencing factor based on the information gained between all models that included a specific influencing factor and all models that excluded that factor. Our results showed that the AHP and RF methods had similar rankings for the top four most important factors, including altitude, distance to faults, distance to waterbodies, and slope, that influence the occurrence of wells with groundwater yields exceeding $10 \text{ m}^3/\text{h}$ in the study area (Table 4.5). The FR identified distance to waterbodies and distance to faults as the first and third most important factors but assigned less weight to altitude and slope. This was because the FR employed a less sophisticated statistical approach, and thus might fail to capture the effects of interaction between the influencing factors. Nevertheless, our analysis indicated that the AHP could be a cost-effective and accurate method to identify the most important influencing factors for policy-making priorities.

Table 4.5. Ranking of influencing factors by a method based on the factor weights. The ranking score ranges from one to eight in descending order of importance

Influencing factor	AHP	FR	RF
Altitude	1	5	2
Distance to faults	2	3	3
Distance to waterbodies	3	1	1
Slope	4	6	4
Geology	5	7	7
Land use	6	2	8
Rainfall	7	4	6
Soil	8	8	5

Our analysis confirmed findings from previous studies regarding the influence of geophysical characteristics on groundwater yield. In particular, the study found that high groundwater yield was mostly observed in areas with an altitude below 100 m, which asserted the impact of gravity on groundwater. A similar study by [Al-Abadi \(2017a\)](#) also showed the occurrence of high groundwater yield in areas with an altitude below 99 m while [Khoshtinat et al. \(2019\)](#) indicated that the lower the altitude, the higher the GWP for their study region. Our study revealed the greater influence of faults as a natural barrier to impeding the occurrence of high groundwater yield, which was in line with a study by [\(Anderson and Bakker, 2008\)](#). However, some previous studies ([Arulbalaji et al., 2019](#); [Arunbose et al., 2021](#); [Falah and Zeinivand, 2019](#)) insisted that high fault density could be an advantage for the rechargeability of groundwater, which was often observed in areas with dominant vertical or mountainous areas with basement rocks ([Chuma et al., 2013](#)). The distance to waterbodies such as rivers, lakes, dams, and springs influenced groundwater yield because surface water was a recharging source of aquifers. The shorter

the distance to waterbodies was, the higher the GWP was. The relationship has also been discussed intensively in previous studies (Chen et al., 2018; Machiwal et al., 2011; Mosavi et al., 2020; Tahmassebi et al., 2016). The slope was also identified as one of the top influencing factors for high groundwater yield in our study with higher yields observed in areas with a slope of below 10°. Similar conclusions were drawn by other studies (Al-Abadi, 2017a; Ganapuram et al., 2009; Jothibas and Anbazhagan, 2016; Kumar and Krishna, 2018).

The GWP with a yield $>10 \text{ m}^3/\text{h}$ of the lowland areas was higher than that of the mountainous areas in Kanchanaburi, where the terrain was flat with a low slope and altitude (Ahmed and Sajjad, 2018; Falah and Zeinivand, 2019; Shao et al., 2020) (Fig. 4.3). This finding was consistent with a previous hydrogeology survey conducted by the DGR in Kanchanaburi province (DGR, 2006). The GWP maps using the RF and ensemble models were considerably similar compared to the AHP and RF, respectively. This can be explained by the Jenks natural break function allowing the equivalent GWPI values to be grouped into a cluster to minimize the variance between classes in the mapping (Papaioannou et al., 2015). The poor GWP zones estimated by the AHP and RF models were 60% of the entire area, which is almost twice as higher as that computed by FR and ensemble. Meanwhile, the moderate GWP represented approximately 30% and 60% of the maps produced using AHP or RF and FR or ensemble models, respectively. The area with high GWP was in a range of 17.89 - 33% from model to model (Fig 4.4). The model selection for GWPZ mapping is an important but difficult decision as it often involves trade-offs among resources, time, expertise, and accuracy. These trade-offs are different for different study areas and objectives. For this study, the study showed that all models achieved similarly good prediction outcomes (Fig. 4.5). However, the RF and FR were more complex, costly, and time-consuming than the AHP model. Therefore, one might be better off just using the AHP model for similar regions where the ground truth data for groundwater yield is not

available. This will save time and costs as well as reduce the complexity. However, in other cases when the accuracy of the GWPZ mapping is a priority, the study recommend the use of complex machine learning models (e.g., RF and artificial neural networks) and/or an ensemble of different models and approaches to improve the overall predictive power, as illustrated by our analysis.

4.2. Exploring nickel contamination risk zones in groundwater in the eastern part of Kanchanaburi province, Thailand using Maxent and AHP

Based on the results from the delineation of groundwater yield potential zones (section 4.1), sections 4.2 and 4.3 focus on in the eastern part of Kanchanaburi province, Thailand, including Nong Prue, Lao Khwan, Bo Phloi, Huai Krachao, Phanom Thuan, Mueang Kanchanaburi, Tha Maka, Tha Muang, Dan Makham Tia districts, where groundwater yield was evaluated high and moderate potential.

4.2.1. Influencing factors on Ni contamination in groundwater

Eight influencing factors, including altitude, distance to road, distance to waterbodies, geology, land use, rainfall, slope, and soil type, were used to delineate the Ni contamination risk zones. [Figure 4a-h](#) shows the details of the influencing factors.

Altitude factor represents the influence of topography on groundwater depth and flow rate ([Condon and Maxwell, 2015](#)). When the flow rate and groundwater depth are significant, groundwater's chemical and physical characteristics can be altered in space and time ([Alizamir et al., 2019](#)). Altitude in the study area can be observed with elevation values ranging from 2 to 1812 meters above sea level, classified into five classes: 2–50 (2,265.64 km²), 50–100 (1,819.74 km²); 100–150 (881.59 km²); 150–200 (578.12 km²); and >200m (1,278.38 km²) ([Fig. 4.6a](#)). The majority of the high elevation zones are on the northwest side.

Distance to roads is considered an essential factor in assessing groundwater

quality (Wang et al., 2018). Road transport activities contribute significantly harmful substances to groundwater through the dry and wet deposition of effluents, dust, and exhaust gases (Uliasz-Misiak et al., 2022). For our case study, distance to roads map was categorized into five classes: 0–2,000 (5,588.13 km²), 2,000–4,000 (954.11 km²), 4,000–6,000 (190.33 km²), 6,000–8,000 (71.61 km²), and >8,000 m (20.54 km²) (Fig. 4.6b).

Waterbodies represent the close relationship between surface water and groundwater in the hydrological cycle. Changes in groundwater's chemical and physical composition are also influenced by the recharge and discharge processes (Lipczynska-Kochany, 2018). Distance to waterbodies factor was categorized into five classes: 0–2,000 (5,081.24 km²), 2,000–4,000 (1,255.16 km²), 4,000–6,000 (254.47 km²), 6,000–8,000 (134.44 km²), and >8,000 m (99.42 km²) (Fig. 4.6c).

Geology plays a significant role in determining the chemical composition of groundwater because groundwater is contained in bedrock aquifer or host sediment (Golkarian and Rahmati, 2018). Twelve geological units are observed in the study area, including Tertiary (Tmm), Devonian-Carboniferous (SDC), Silurian-Devonian (SD), Quaternary (Q), Permian (Pr), Pre-Cambrian (PE), Ordovician (O), Cretaceous (Kgr), Jurassic (J), Cambrian-Ordovician (EO), Cambrian (E), Carboniferous-Permian (CPk), in which Q covers the highest area (4,413.86 km²), followed by SDC (474.25 km²), O (421.22 km²), Pr (330.14 km²), Tr (285.74 km²) (Fig. 4.6d).

Land use reflects human activities on the land surface (Zhang et al., 2019). The wastes from human activities affect the quality of groundwater (McLay et al., 2001). There are five main land use types in the study area, including urban land (446 km²), agricultural land (4,253 km²), miscellaneous (362 km²), forest land (1688 km²), and waterbody (76 km²) (Fig. 4.6e).

Rainfall is known as a recharge source of groundwater, meaning its chemical

components in the water can affect groundwater quality (Ali et al., 2020). In this study, the rainfall data was divided into five different regions as follows: <1,500 (149.73 km²), 1,500–1,650 (1,692.15 km²), 1,650–1,800 (3,859.18 km²), 1,800–1,950 (1,062.97 km²), and >1,950 mm/year (60.7 km²) (Fig. 4.6f).

Slope reflects the direction and the speed of surface runoff, influencing the weathering and surface corrosion processes. Therefore, slope also affects surface water's and groundwater's chemical and physical composition (Arulbalaji et al., 2019). Slope value varies between 0° and 70° in the study area, classified into five classes: 0°–3° (1,904.08 km²), 3°–6° (2,340.29 km²), 6°–10° (1,238.63 km²), 10°–16° (575.26 km²), and >16° (765.22 km²) (Fig. 4.6g). Regions with high slopes are concentrated in the western hilly areas.

Soil type is known as a natural filter of the earth's crust for groundwater, meaning chemicals can be partially trapped as groundwater seeps into the soil (Keesstra et al., 2012). Fourteen different texture types are found in the study areas, including gravelly sandy loam (314.28 km²), loamy sand (462.70 km²), gravelly sandy clay loam (519.27 km²), sandy loam (2,759.57 km²), clay loam (1,987.16 km²), silt loam (503.45 km²), sandy clay loam (88.21 km²), loam (334.97 km²), silty clay loam (329.95 km²), clayey sand (11,189.83 km²), water (829.28 km²), rock complex (33.78 km²), coarse sandy loam (1.83 km²), silt (32.13 km²) (Fig. 4.6h).

Fig. 4.6. Influencing factors: (a) altitude, (b) distance to roads, (c) distance to waterbodies, (d) geology, (e) land use, (f) rainfall, (g) slope, (h) soil type

4.2.2. Application of Maxent technique to estimate the contribution level and predicted value of influencing factors over Ni contamination.

The Maxent approach provides information about the contribution level of influencing factors to the occurrence ability of Ni contamination in groundwater and the predicted value of classes of influencing factors (Wahyudi et al., 2013). Fig. 4.7 illustrates the contribution level of influencing factors to Ni contamination determined by the Maxent technique. The result shows land use has the highest contribution of 65.4% to the delineation of Ni contamination in groundwater, followed by soil type (14.7%), slope (7.7%), and altitude (4.8%). The other factors contribute to the model by approximately 2%. Additionally, the impact of influencing factors on Ni contamination in groundwater is displayed in Fig. 4.8. The high response of Ni contamination in groundwater occurred at altitude of 0-50 m, distance to roads of 0-2000 m, distance to waterbodies of >8000 m, geology unit of Pre-Cambrian, land use of urban land, slope of 0°-3°, soil type of clay loam.

Fig. 4.7. Role of influencing factors in predicting Ni contamination in groundwater

Fig. 4.8. The predicted values for classes of influencing factors on the occurrence ability of Ni contamination in groundwater

4.2.3. Application of AHP for calculating the weight of influencing factors

A pairwise comparison matrix was established from the contribution level of influencing factors to the occurrence ability of Ni contamination in groundwater (Table 4.6). Table 4.7 presents the weighted criteria of influencing factors for Ni contamination prediction in groundwater. The rank of classes was set based on the predictive value (Table 4.8). The result of the AHP analysis indicates that the consistency ratio of the matrix was 0.049. This consistency ratio proves that the analytical result of the model was acceptable (Arulbalaji et al., 2019; Saaty, 1990). Among influencing factors, land use had the highest AHP weight at 48.711, followed by soil type and geology. The other influencing factors had the same AHP weight of 4.287.

Table 4.6. Pairwise comparison matrix of influencing factors

Factors	Altitude	DtR	DtW	Geology	Land use	Rainfall	Slope	Soil type	Criteria

4.2.4. Map of Ni contamination risk zone in groundwater

Groundwater is known as a drinking water source in many regions of the world. Using groundwater with high Ni concentrations for domestic purposes will lead to cancer risk and health complications (Egbueri, 2020). Thus, a map of groundwater's Ni contamination risk zones is necessary in any region of the world. In this study, the map of groundwater's Ni contamination risk zone was identified by the potential contamination index to delineate the Ni contamination risk zone in groundwater. The output map was spatially categorized as low, moderate, and high zones (Fig. 4.9). Overall, 24.79% of the area (1691.82 km²) was very low contamination risk of Ni, whereas the zone of high Ni contamination risk accounted for around 6.56% (447.65 km²). Moderate contamination risk zone of Ni occupied 68.65% of the study area (Table 4.9).

Fig. 4.9. Map of Ni contamination risk zones in groundwater

Table 4.9. Statistics of Ni contamination risk zones in groundwater in the study area

Level	Number of pixels	Area (km ²)	Percentage (%)
Low risk	1879835	1691.85	24.79
Moderate risk	5204419	4683.98	68.65
High risk	497389	447.65	6.56

4.2.5. Validation

The ROC technique and statistical indicators were utilized to confirm the Ni contamination risk zones in groundwater. A total of 54 groundwater samples (30% of the database) were used to validate the model's performance validation and the accuracy of the output map. The validation results clearly show that the model's AUC value index was 0.86 (Fig. 4.10), and the accuracy of the resulting map was 85%. The results of other statistical indicators are presented in Table 4.10. From the model validation result and the accuracy of the output map, it can be concluded that combining the maxent method to set the weighted criteria and the AHP technique to delineate the heavy metal contamination risk zone in groundwater is an effective model.

Fig. 4.10. Model performance

TP	TN	FP	FN	PPV	NPV	Sensitivity	Specificity	Accuracy
6	40	4	4	0.60	0.91	0.60	0.91	0.85

4.2.6. Discussion

Mapping the Ni contamination risk zone in groundwater is necessary for the long-term management of water resources. In this study, the maxent algorithm was selected to replace the expert's opinions in the AHP technique. By comparison to the previous studies (Arunbose et al., 2021; Azimi et al., 2018; Chakraborty et al., 2016), the criteria score has been given based on the contribution level of influencing factor to Ni contamination in groundwater from the output of maxent approach, which help to eliminate the subjective from judges as using the AHP technique. Additionally, the limitation of controlling factor was also broken compared to previous studies on groundwater vulnerability and risk (Barzegar et al., 2018). In our case study, eight influencing factors was considered conditional variables for predicting Ni contamination risk, including altitude, distance to roads, distance to waterbodies,

geology, land use, rainfall, slope, and soil type, which had never done in assessing groundwater contamination risk.

Regarding sensitivity analysis, the model shows the role of influencing factors in determining the Ni contamination, in which land use is the influencing factor with the largest contribution, followed by soil type. The analysis results indicated that land use and soil type factors explain approximately 67.8% variation in Ni contamination in groundwater. Our analysis unveiled the correlation between influencing factors and Ni contamination risk. The higher the altitude value is, the lower the Ni contamination is. Distance to roads and slopes are inversely proportional to the Ni contamination risk, while distance to water bodies is proportional to the Ni contamination risk. Geologically, the Ni contamination risk in groundwater of the Pre-Cambrian unit is higher than that of other units. Regarding land use, the urban areas were defined as the highest-risk zone with Ni contamination in groundwater, followed by the miscellaneous zones, agricultural zones, and forest land. Indeed, human activities were the leading cause of Ni contamination in groundwater (Egbueri, 2020; Khatri and Tyagi, 2015). In terms of soil type, the Ni contamination in groundwater of locations with clay loam, sandy loam, and clay loam is higher than that of locations with other soil textures. The findings of the present study were consistent with previous studies on the causes of groundwater contamination (Egbueri, 2020; Sajedi-Hosseini et al., 2018; Singha et al., 2020; Tiankao and Chotpantararat, 2018). In addition, our study indicated that the effect of rainfall is the same in any value.

Compared to other administrative districts, the groundwater in the Mueang Kanchanaburi district was found to be a high Ni contamination risk, raising concern over groundwater pollution management, particularly in urban areas. Therefore, strict policies for discharging waste materials should be applied in this region (Hu et al., 2014). The Ni contamination in groundwater used in the present study is considered

a striking example to show the geographical distribution of possibly polluted regions and to investigate the critical cause in identifying contaminated risk areas using the Maxent and AHP techniques. The AUC value indicated that the used model was a relatively effective solution for mapping Ni contamination susceptibility in groundwater.

4.3. Deciphering groundwater quality in the eastern part of Kanchanaburi province, Thailand using RF and ANN

4.3.1. Groundwater quality in Kanchanaburi

Table 4.11 provides information on twelve physicochemical parameters in groundwater samples in Kanchanaburi, Thailand. The mean value of Ca^{2+} (97.09 mg/l) and HCO_3^- (461.94 mg/l) in the groundwater of the study area were the above-recommended limits. The Kolmogorov-Smirnov test shows the p-value of physicochemical parameters ranging from 0 to 0.002. In terms of calculating the EWQI, the entropy weight of NO_3^- was the highest, followed by SO_4^{2-} , Cl^- , K^+ , Na^+ , EC, Mg^{2+} , Ca^{2+} , TH, TDS, HCO_3^- , and pH. Groundwater parameters exceeded the allowed limit in some groundwater samples except for the Cl^- . The concentration of HCO_3^- , Ca^{2+} , and Mg^{2+} were normally found above the allowed limit with a number of 173, 132, and 70 groundwater samples, respectively. Regarding hydrogeochemical properties, alkaline earth (Mg+Ca) dominated over alkalis (Na+K), while, and weak acids (HCO_3^-) and strong acids (SO_4+Cl) were not clearly distinguished in distribution (Fig. 4.11). The concentration of Mg and Ca increased when the concentration of alkalis (Na+K) decreased. The groundwater samples were predominated by Ca-Cl, mixed Ca-Mg-Cl, mixed Ca-Mg- HCO_3^- , and Ca- HCO_3^- . The correlation matrix of physicochemical parameters in groundwater is shown in Fig. 4.12. Groundwater parameters were positively correlated with the normalized EWQI except for the pH. Out of these, the Na^+ , HCO_3^- , SO_4^{2-} , TH, Ca^{2+} , EC, Mg^{2+} , Cl^- , and TDS had more than a correlation value of 0.5. The spatial distribution of

groundwater parameters is displayed in Fig. 4.13.

Table 4.11. Parameters relevant to groundwater samples

4.3.2. Application of the RF and ANN with cross-validation and bootstrap in deciphering groundwater quality

The regression task of RF and ANN was conducted to predict the normalized EWQI in this study. Then, the normalized EWQI was deciphered into groundwater quality zones. The CV and B techniques were directly integrated into the RF and ANN algorithms, called RF-CV, RF-B, ANN-CV, and ANN-B models, respectively. For this task, the RF model was optimized from the error estimate to determine the n-tree (that is., the optimal number of trees). The optimal number of n-tree was 36 and 134 for the RF-CV and RF-B, respectively (Fig. 4.14). Compared to the RF, the ANN was established based on back-propagated feed-forward processes using the neural networks. Both the ANN-CV and ANN-B were optimal when the hidden layer was determined to be three nodes and a weight decay of 0.1 (Fig. 4.15). Fig. 4.16 presents the groundwater quality map using the RF-CV, RF-B, ANN-CV, and ANN-B models. For the RF-CV, 64.78% and 29.39% of the study area were good and very good groundwater quality, respectively. Meanwhile, only 0.58% and 0.08% were poor and very poor groundwater quality, respectively. The remaining 5.17% was designated to be moderate groundwater quality. For the RF-B, 62.92% and 30.24% of the study area were deciphered into good and very good groundwater quality. Moderate, poor, and very poor groundwater quality zones accounted for 6.23 %, 0.56%, and 0.05% of the whole region, respectively (Table 4.12). For the ANN-CV model, 41.94% and 52.66% of the total area were estimated to be of very good and good groundwater quality. Moderate and poor groundwater quality areas account for 4.50% and 0.90% of the total area, respectively. For the ANN-B, 53.46% and 39.90% of the total area were deciphered to be good and very good groundwater quality. Moderate, and poor zones constitute 5.67%, and 0.97% of the total area, respectively (Table 4.12).

Table 4.12. Statistical area in the models

Groundwater quality	RF-CV		RF-B		ANN-CV		ANN-B	
	Pixels	%	Pixels	%	Pixels	%	Pixels	%
Very good	2228061	29.39	2292578	30.24	3180026	41.94	3025163	39.90
Good	4911720	64.78	4771306	62.92	3992212	52.66	4053478	53.46
Moderate	391682	5.17	472007	6.23	341541	4.5	429246	5.67
Poor	43926	0.58	42205	0.56	67864	0.9	73756	0.97
Very poor	6254	0.08	3547	0.05	0	0.0	0	0.0

4.3.3. Validation

The validation process plays a key role to confirm the performance of machine learning models, which assists in choosing the best predicting model for mapping groundwater quality. Table 4.13 presents the validation indexes estimated by the models. Regarding the values of RMSE and MAE, the ANN-B model was the highest (RMSE = 0.101 and MAE = 0.065), followed by ANN-CV (RMSE = 0.098 and MAE = 0.061), RF-B (RMSE = 0.078 and MAE = 0.047), ANN-CV (RMSE = 0.067 and MAE = 0.043). However, the R^2 value of RF-CV was the highest (0.873) compared to the other three models. The RF-V's R^2 of 0.081 was second only to that of the RF-CV. The ANN-CV and ANN-B placed third and fourth when comparing the R^2 values with 0.709 and 0.617, respectively.

Table 4.13. Validation of the models

Models	RMSE	R ²	MAE
RF-CV	0.067	0.873	0.043
RF-B	0.078	0.801	0.047
ANN-CV	0.098	0.709	0.061
ANN-B	0.101	0.617	0.065

4.3.4. Role of parameters in deciphering the groundwater quality

A stable and powerful model is normally decided by input variables (Şakar, 2018). Therefore, the importance of groundwater parameters needs revelation to decipher the groundwater quality maps, which helps to determine the contribution of physiochemical parameters to normalized EWQI. There was a great difference among models regarding the role of groundwater parameters in predicting the normalized EWQI (Table 4.14). In the RF models, TDS was the most important contribution to predicting the normalized EWQI (100) while the contribution of pH was zero. In the ANN-CV, the important parameters included pH (100), Na⁺ (30.25%), Cl⁻ (29.54%), SO₄²⁻ (25.31%), Ca²⁺ (20.86%), and NO₃⁻ (20.79%). In the ANN-B, pH (100%), SO₄²⁻ (29.05%), and NO₃⁻ (28.39%) were the important parameters in deciphering groundwater quality.

Table 4.14. Contribution levels of groundwater parameters in deciphering the normalized EWQI

Model	RF-CV (%)	RF-B (%)	ANN-CV (%)	ANN-B (%)
Total dissolved solids	100.00	100.00	4.17	15.85
Chloride	0.31	15.62	29.54	8.94
Sulfate	4.85	14.15	25.31	29.05
Total hardness	1.17	13.25	12.58	4.46
Bicarbonate	2.54	10.95	1.87	13.13
Calcium	5.99	10.85	20.86	8.42
Nitrate	7.57	10.70	20.79	28.39
Sodium	0.75	5.61	30.25	7.53
Electric conductivity	2.32	4.36	0.00	0
Potassium	2.73	3.68	18.833	11.27
Magnesium	3.70	3.37	17.63	1.54
pH	0.00	0.00	100.00	100.00

4.3.5. Discussions

The protection of groundwater resources is a vital mission in many countries, especially where groundwater is used mainly for domestic and productive activities (Doveri et al., 2015). As a result, evaluating and delineating the groundwater quality zones is necessary to orient the groundwater use and management plan. For this reason, hydrologists have attempted to find an appropriate approach for delineating groundwater quality zones. This study pioneered integrating the CV and B techniques with two famous algorithms with high accuracy (RF and ANN). For this integration, four ML models were considered in deciphering groundwater quality in the eastern part of Kanchanaburi province, Thailand. The physicochemical parameter was referred to the previous publications in prestigious journals. In the comparison with previous studies (Adimalla, 2021; Amiri et al., 2014; Kumar and Augustine, 2022; Raheja et al., 2022; Singha et al., 2021), the normalized EWQI applied to delineate the groundwater quality zones, which contributes a general guideline for global groundwater investigations.

Our study indicated that there is a dramatic difference in the role of groundwater parameters in predicting the normalized EWQI in the four models, which can be explained by the nature of the approaches themselves. The RF models use decision trees to deal with data (Belgiu et al., 2016). While the ANN models are developed based on the neural network (Noori et al., 2010). In this analysis, our study found that TDS was the most important parameter in the RF models while pH was the most important parameter in the ANN models, which was not the same as a previous study by Singha et al. (2021). For this difference, the CV and B techniques were applied to the initial dataset while Singha et al. (2021) divided the initial dataset into two subsets with different ratios for the training and testing missions. This study indicated that the RF models were better than the ANN models in deciphering groundwater quality zones, which coincided with

some publications (Bui et al., 2020; Mallick et al., 2021; Nafouanti et al., 2021). In addition, the CV technique outperforms the B technique, which could be explained by the difference in building subsets (Brodeur et al., 2020). The CV technique uses the entire initial database while the B technique applies only a part of the initial database. Among four models, the most optimal model was the RF-CV (RMSE = 0.067, R^2 = 0.873, MAE = 0.043), followed by the RF-B (RMSE = 0.078, R^2 = 0.801, MAE = 0.047), ANN-CV (RMSE = 0.098, R^2 = 0.709, MAE = 0.061), and ANN-B (RMSE = 0.101, R^2 = 0.671, MAE = 0.065). As a result, this study proposes the RF-CV model could apply to map groundwater quality not only in Thailand but also in other parts of the world. Our study also indicated that the performance of the RF models depends on the number of trees (Bernard et al., 2009). While the performance of the RF models depends on the number of intermediate nodes (Zannou et al., 2021).

According to the RF-CV model, approximately 94% of the study's area was good to very good groundwater quality. The rest of the territory (about 6%) was medium, poor, and very poor groundwater quality, which was distributed in the middle regions of the study area. In the comparison with the land use map, poor, and very poor groundwater quality occurred in the agricultural and urban regions, which agrees with a study by Sajedi-Hosseini et al. (2018). Agricultural activities (like lime and inorganic fertilizer practices), limestone quarries, and geological settings were the main reasons leading to poor quality in the study area (Deshmukh, 2013; Ghaffari et al., 2021; Saha et al., 2019; Sridharan and Senthil Nathan, 2017). This study suggests that zones with good and very good groundwater quality can be used for daily purposes of local people while the zones classified very poor, poor and moderate groundwater quality should be used for agricultural or industrial purposes. However, the calcium, magnesium, and bicarbonate in groundwater should be handled before drinking because our physicochemical analysis showed that groundwater in the study area was mainly polluted by Ca^{2+} , HCO_3^- , Mg^{2+} .

Chapter 5. CONCLUSION AND SUSGESTION

5.1. Conclusion

The AHP, FR, and RF models were used in this study to represent the expert decision, statistical, and machine learning approaches for the GWPZ mapping method comparison. In particular, the study aimed to map the potential of achieving a groundwater yield above 10 m³/h for Kanchanaburi Province in Thailand. An ensemble of the three models was also created and compared to the individual models in the mapping of GWPZ. The results showed that all models achieved similarly good prediction with an AUC value of 0.72, 0.74, 0.76, and 0.80 for the AHP, FR, RF, and ensemble models, respectively. The ensemble model improved the overall predictive power and performed better in areas where all the individual models failed. This study illustrated the usefulness of the ensemble of models from different approaches in mapping GWPZ and discussed how future studies can adopt similar approaches to improve the delineation of GWPZ for policy foci in sustainable groundwater management. This study recommends that the GWPZ map achieved by the ensemble model be integrated with the surface water planning map, land use planning map, and economic map to assist scientists, policymakers, and managers in Kanchanaburi Province, Thailand, in inclusive and sustainable development.

This study attempted to delineate the Ni contamination risk zones using a hybrid model of the Maxent and AHP modeling approach. This model works well with an AUC value of 0.86 and an accuracy of 0.85 in delineating the geographical distribution of Ni contamination risk in groundwater. Eight factors, including altitude, distance to roads, distance to waterbodies, geology, land use, rainfall, slope, and soil type, were selected to set up the model. Among the eight investigated factors in this study, land use was the most relevant factor for identifying possibly contaminated locations, followed by soil type. The urban area was the most likely Ni

contamination in groundwater. The map of Ni contamination risk zones in groundwater could provide information for residents and decision-makers in using groundwater resources for various purposes. It could help Thailand's groundwater resource management agencies grasp the practical basis and find solutions for the protection of groundwater resources in areas with high Ni contamination risk.

This study evaluated groundwater quality in the eastern part of Kanchanaburi province and developed four ML models by integrated the RF and ANN algorithms with the CV and B techniques. The EWQI was converted into the normalized EWQI. The study found that groundwater quality in the study area was polluted with calcium, magnesium, and bicarbonate and that the RF-CV was the best in deciphering the groundwater quality map, compared to the RF-B, ANN-CV, and ANN-B. In the RF-CV, TDS was the most important parameter while other parameters were little contribution to predicting the normalized EWQI. The groundwater quality zones were classified into five levels in the study area. Regarding the best model (RF-CV), poor and very poor groundwater quality occurred in the agricultural areas. The results from the present study can be a reference document for developing and mapping groundwater quality in the future.

5.2. Suggestion

For mapping groundwater yield potential, the AHP, FR, and RF models were used in this case study to represent the expert decision, statistical, and machine learning approaches in GWPZ mapping. However, this study acknowledges that these approaches are broad topics on their own and thus this study's comparison of the particular models might not be representative. This study strongly encourages future studies to explore different model combinations to fortify this study's initial findings, as this study pioneered the research. For studies that wish to follow this study's approach to GWPZ mapping, this study recommends that they first employ the AHP

methods to generate the GWPZ map and then collect a small set of ground truth data to validate the model results. If the results do not meet expectations, more ground truth data can be collected to create the FR model, and if further accuracy improvement is required, much more data should be collected to build the RF model. As illustrated by this study's analysis, one should always attempt ensemble models when data is available to improve the overall predictive power. Additionally, this study also suggests that groundwater resources in the Western part of Kanchanaburi, including Sangkhla Buri, Thong Pha Phum, Si Sawat, Sai Yok districts, should be strictly protected due to the low groundwater yield potential and that in the Eastern part of the province, including Nong Prue, Lao Khan, Bo Phloi, Huai Krachrao, Muong Kanchanaburi, Tha Muang, Tha Maka, Dan Makham districts, can exploit for purposes of socio-economic development.

For mapping contamination risk in groundwater, this study recommends that the hybrid model between Maxent and AHP can also be applied to investigate other heavy metal elements in groundwater because of its own advantages. The input influencing factors of the model could be easily collected from the field, government agencies, and free satellite images. Consequently, budget, human labor, and time could be saved using this process. However, Ni concentration depends on the accuracy of the analysis instrument. Although the modeling approach for mapping the Ni contamination risk zone gives a good result, groundwater is constantly moving, so the groundwater quality at different times will be different. Therefore, the assessment of Ni content in groundwater should be carried out regularly in the future. Additionally, the present model still has limitations in terms of the data on solid wastes, wastewater, waste gas, surface water pollution, and soil contamination. Hence, these influencing factors should be used to control the future model. This study also recommends local people in areas with a high risk of groundwater pollution, especially urban regions, should not use groundwater for

daily drinking purposes.

For mapping groundwater quality, this study suggests that the RF-CV model should be applied to map groundwater quality not only in Thailand but also in other parts of the world. However, this study focuses only on the physicochemical parameters to estimate the EWQI, the study recommends that future studies should consider the heavy metal elements in deciphering groundwater quality maps. Additionally, this study limits in considering the RF and ANN combined with the cross-validation and bootstrap, therefore an exploration of the performance of other machine learning is needed to be conducted in the future to determine the best model for deciphering groundwater quality map. Simultaneously, groundwater samples were collected at a time due to the limitation of financial support, therefore, the seasonal variations of groundwater quality are not considered, which can affect the results.

From the results, groundwater agencies can release policies on groundwater. It can be done by publicizing the list of restricted areas from the exploitation of groundwater and orienting in reasonable groundwater exploitation and usage with different purposes.

Structure of algorithm

Algorithm 1. Random forest for predicting GW yield

```

1: # Install package “randomForest” and “Java environment”
2: # Import databases
3: # Set training and testing dataset
3: # Construct Random Forest model
4: RF = randomForest(‘environmental factors’, ‘train data’, 'ntree', 'cross-validation')
5: # Get the map
6: plot(RF)

```

Algorithm 2. Maxent approach

```

1: # Install package “SDM” and “Java environment”
2: # Import databases
3: # Construct maxent model
4: MX = max(‘environmental factors’, ‘train data’)
5: # Get the contribution variable
6: plot(MX)
7: # Get the predicted value
8: response(MX)

```

Algorithm 3. Random forest for deciphering GW quality

```

1: # Install package “randomForest” and “plyr”
2: # Import databases
3: # Set Cross-validation
4: # Set Bootstrap
5: # Construct RF-CV and RF-B models
6: RF_CV = train(‘influencing factors’, ‘dataset’, 'RF', 'trControl = method'CV', 'number =5")
7: RF_B = train(‘influencing factors’, ‘dataset’, 'RF', 'trControl = method'boot',

```

```

'number =100")
8: # Determine the best model
9: which.min(plot(RF_CV$finalModel,fallen.leaves = F))
10: which.min(plot(RF_B$finalModel,fallen.leaves = F))
11: Get the maps
12: plot(RF_CV)
13: plot(RF_B)
14: # Determine the important value
15: varImp(RF_CV)
16: varImp(RF_B)

```

Algorithm 4. Artificial Neural Networks for deciphering GW quality

```

1: # Install package "neuralnet"
2: # Import databases
3: # Set Cross-validation
4: # Set Bootstrap
5: # Construct ANN-CV and ANN-B models
6: ANN_CV = train('influencing factors', 'dataset', 'nnet', 'trControl = method'CV',
'number =5")
7: ANN_B = train('influencing factors', 'dataset', 'nnet', 'trControl = method'boot',
'number =100")
8: Get the maps
9: plot(ANN_CV)
10: plot(ANN_B)
11: # Determine the important value
12: varImp(ANN_CV)
13: varImp(ANN_B)

```

VITA

NAME NGUYEN NGOC THANH

DATE OF BIRTH 27 February 1990

PLACE OF BIRTH Quang Binh - Vietnam

INSTITUTIONS ATTENDED Interdisciplinary Program in Environmental Science.
Graduate School, Chulalongkorn University

HOME ADDRESS 53 Tran Nguyen Dan, Hue city, Vietnam

PUBLICATION

- 1) Thanh, N. N., Thunyawatcharakul, P., Ngu, N. H., & Chotpantararat, S. (2022). Global review of groundwater potential models in the last decade: parameters, model techniques, and validation. *Journal of Hydrology*, 128501.
- 2) Thanh, N. N., Chotpantararat, S., Trung, N. H., & Ngu, N. H. (2022). Mapping groundwater potential zones in Kanchanaburi Province, Thailand by integrating of analytic hierarchy process, frequency ratio, and random forest. *Ecological Indicators*, 145, 109591. [Q1, IF 6.2]
