KEYWORD:

Dissaya Sukaudom : VEGETATION DYNAMICS AND SEA-LEVEL CHANGES IN THE UPPER GULF OF THAILAND. Advisor: Asst. Prof. AKKANEEWUT JIRAPINYAKUL, Ph.D.
Co-advisor: Asst. Prof. Paramita Punwong, Ph.D.

Climate change plays a role in sea level fluctuation, either transgression or regression leads to coastline evolution. Samut Sakhon province is located on the coast in the upper Gulf of Thailand therefore past sea-level studies in this area can contribute information to a better understanding of sediment dynamics and assess future coastline development. The study site provides sedimentary sequences consisting of 9 sediment units from 25.5-7.2 m. DBS, results of LOI, Ti/Ca, and Zr/Rb ratio, grain size, and pollen analysis were interpreted together with radiocarbon dating to reconstruct past environments in the study site. The past environment in Samut Sakhon site can be divided into two parts in the late Pleistocene (26.5-22.7 cal ka BP), Samut Sakhon was temporal exposure during dry conditions, and in the mid/late Holocene (5.4-1.1 cal ka BP), mangrove forests grew due to sea level transgression at 5.4-4.4 cal ka BP before being transferred into the back-mangrove forest at 4.4-4.2 cal ka BP and wetland during sea level regression at 4.2-2.3 cal ka BP, respectively. Samut Sakhon site was likely to be a brackish area thereafter at 2.3-1.1 cal ka BP. To improve the level accuracy and decrease data discrepancies, autonomous level monitoring, and differential global positioning systems should be used in combination with future research.

ACKNOWLEDGEMENTS

I would like to express my sincere thanks to my thesis advisor, Assistant Professor Akkaneewut Jirapinyakul, Ph.D. for his invaluable help and constant encouragement throughout the course of this research. I am most grateful for his advice and guidelines not only research methodologies but also many other methodologies in life. I would not have achieved this far without all the support that I have always received from him.

Moreover, I am grateful for the advice and knowledge of palynological study and laboratory techniques that I received from my co-advisor, Assistant Professor Paramita Punwong, Ph.D. from the Faculty of Environment and Resource Studies, Mahidol University.

Finally, I am most grateful for the support from my family and friends who assisted me throughout the period of this research.

Dissaya Sukaudom

CHAPTER 1

INTRODUCTION

1.1 Background

Climate change plays a role in sea level fluctuation. Either transgression or regression may subsequently change coastal sediment dynamics, leading to coastline development (Surakiatchai et al., 2018; Zhang et al., 2022; Zhang et al., 2023). Furthermore, coastal erosion rates and saltwater intrusion caused by rising sea levels alter the vegetation dynamics along the coastline (Choowong et al., 2004; Surakiatchai et al., 2018). These influences of sea level changes will dramatically impact the livelihoods, including humans, animals, and plants, along the coastline. The study of past sea level changes can contribute information to a better understanding of sediment dynamics and assess future coastline development for sustainability management in the coastal area.

The Gulf of Thailand has been considered to be a crucial area for sea level change studies (Hanebuth et al., 2000; Horton et al., 2005; Chabangborn et al., 2020). It is located in a tropical climate and is unaffected by isostatic movement. Moreover, the evidence of tectonic activities is indeterminable in the Gulf of Thailand (Horton et al., 2005; Oliver & Terry, 2019). Therefore, the sea level changes in the Gulf of Thailand are possibly caused by the eustatic changes (Horton et al., 2005).

Samut Sakhon province is located on the coast in the lower central plain that considered to be a potential area for hydrocarbon accumulation, 5 km north of the upper Gulf of Thailand (Sinsakul, 2000). Moreover, the neighborhood area at the coast in Samut Sakhon is mostly shrimp farms and open pits where topsoil was dug out and shows a clear sediment profile that is suitable for paleoenvironmental study.

The sea level changes along the Gulf of Thailand have been reconstructed by various proxies, i.e., the radiocarbon dating of peat layer or shell attached to sea notch (Somboon, 1990; Tjia, 1996; Hutangkura, 2014; Surakiatchai et al., 2018), geomorphology (Bird et al., 2007; Tamura et al., 2009; Li et al., 2012; Surakiatchai et al., 2018), sedimentology, and palynology (Nudnara, 2019; Chabangborn et al., 2020; Sainakum et al., 2021). Although many studies have been done to date, more information is necessitated to constrain the uncertainty of environmental reconstruction.

1.2 Research objectives

To investigate the temporal variabilities of sea level, vegetation dynamics, and coastal evolution in the upper Gulf of Thailand.

1.3 Scope of the study

This study focuses on investigating vegetation dynamics associated with the sea level changes at an open pit in Samut Sakorn province ($13^{\circ} 32.145'N$ to $13^{\circ} 32.155'N$ and $100^{\circ} 21.684'E$ to $100^{\circ} 21.725'E$). The open pit covering an area of approximately 0.42 km^2 , located approximately 5 km north of the upper Gulf of Thailand. Sediment samples were collected from the bottom to the top of the open pit (25.48-7.20 mDBS). A total of 145 samples were further studied at the Department of Geology, Faculty of Science, Chulalongkorn University. For laboratory analysis, 145 samples from consecutive 10 cm were used for Loss on ignition (LOI) and X-ray Fluorescence Spectroscopy (XRF), 11 samples were used for radiocarbon dating (C^{14}), 60 samples were used for pollen analysis, and 73 samples were used for grain size analysis.

CHAPTER 2

LITERATURE REVIEW

2.1 Mangrove response

Mangrove environments are dominant assemblages of trees and shrubs that developed special physiological and morphological adaptations in saline tidal wetlands fringing the sheltered tropical shores (Santisuk, 1983; Ellison, 2008; Li et al., 2012; Englong et al., 2019). The development of a mangrove community depends on several environmental factors, including tidal flooding, maximum wave height or inundation, soil type, and salinity (Santisuk, 1983; Li et al., 2012).

Watson (1928) classified the total water level that occurs on normally dry ground as a result of the storm tide as tidal inundation into 5 classes associated with the distribution of mangrove trees and shrubs in Malaya (Table 1).

Table 1 Tidal inundation class from Watson (1928)

Class	Flood type	Frequency (times per month)
1	All high tides	56 - 62
2	Medium high tides	45 - 59
3	Normal high tides	20 - 45
4	Spring tides	2 - 20
5	Abnormal of equinoctial tides	0 - 2

According to Watson's inundation classes, mangroves can be divided into 2 subdivisions, swampy mangroves or mangroves and back mangroves from inundation classes 1-3 and 4-5, respectively (Watson, 1928; Santisuk, 1983). Swampy mangroves or mangroves are normally submerged and covered by sea water during high tide, while back mangroves are only submerged during very high tides (Santisuk, 1983).

Santisuk (1983) developed Watson's inundation classes associated with mangrove distribution in Thailand (Table 2).

Mangrove trees and shrubs can be interpreted by palynology which is the study of pollen and spores of plants. Pollen and spores contain sporopollenin which is a special structure of the durable outer (exine) walls of spores and pollen grains that can protect itself from external factors such as temperature, acidity, and alkalinity. This property together with their high productivity made pollen and spores are well preserved in sediment and a suitable tool for the reconstruction of the past environments (Punwong, 2007).

2.2 History of sea level changes in the Gulf of Thailand

Sea level changes have been considered to be possibly caused by isostatic rebound, tectonic adjustment, and eustatic changes. Since the Gulf of Thailand is in a tropical climate and far from ice sheet margins (Long et al., 2001), it is not impacted by the isostatic adjustment (Horton et al., 2005; Zhang et al., 2022). Moreover, the evidence of tectonic movement is indeterminable in the Gulf of Thailand. Therefore, it has been considered to be stable, and tectonic movement can be neglectable (Tjia, 1996; Horton

et al., 2005; Jirapinyakul et al., 2023). Consequently, the Gulf of Thailand is a crucial area for eustatic changes (Sainakum et al., 2021). The sea level changes along the Gulf of Thailand and surrounding areas have been reconstructed based on various methods, i.e., geomorphology (Choowong, 2002; Dusitapirom et al., 2008; Surakiatchai et al., 2018; Oliver & Terry, 2019), Diatom (Zhang et al., 2023), radiocarbon dating of peat layers (Hesp et al., 1998; Bird et al., 2007), X-Ray Fluorescence, sedimentology and palynology (Somboon, 1988, 1990; Somboon & Thiramongkol, 1992; Nudnara, 2019; Chabangborn et al., 2020).

The global sea level was approximately 120 meters below the present mean sea level (MSL) during the Last Glacial Maximum (23.0 to 19.0 cal ka BP) when glaciers and ice sheets in the high latitudes reached their maximum (Hanebuth et al., 2000b; Tanabe et al., 2003; Zong, 2013) (Figures 1 and 2). The sea level low stand can be explained by the transformation of ocean water to deposit on the continental ice sheets caused by the changing Earth's orbit (Bowen, 2009). The sea level in the Gulf of Thailand was also lowering, exposing the Sunda shelf, connecting the Southeast Asian mainland and Indonesian archipelagos (Hanebuth et al., 2000a; Bird et al., 2007). The exposure of Sundaland was a land bridge for the migration of animals and humans to the Indonesian archipelagos and Australia (Zhang et al., 2022).

Sea levels rapidly increased during the early Holocene (approximately 11.7 to 8.2 ka BP) (Geyh et al., 1979; Hanebuth et al., 2000a; Horton et al., 2005; Hutangkura, 2014). Reconstruction of the sea level based on pollen and sediments from the Malay-Thai peninsula reveals the sea level rise at 9,700 cal years BP and reaches its highstand at 4.8–4.4 cal ka BP (Horton et al., 2005). The reconstructed transgression in the Malay-Thai peninsula has a slight lead or lag in time regarding the other studies from the vicinity areas, e.g., records of *Sonneratia alba* and *Sonneratia caseolaris*, mangrove pollen taxa, that appeared in the sediment at 8.3 ka cal year BP, Mekong River Delta, Cambodia (Li

et al., 2012), and radiocarbon dating of peat layer in Singapore (Bird et al., 2007). Pollen records of Chao Phraya delta suggest a submerge most of the Chao Phraya delta up to the north of Ayutthaya, Thailand, at 7.3–6.5 ka BP (Somboon & Thiramongkol, 1992) (Figure 3). In addition, the recent studies based on multi-proxies obtained from Thale Noi, Thailand, suggested that the sea level fluctuation at 8.2 ka during the early Holocene (Chabangborn et al., 2020). However, all these studies agree on the rapid rise of sea levels during the early Holocene.

Several studies suggest that the sea level reached its high stand of c. 2-4 m during the mid-Holocene (8.0-4.0 cal ka BP) (Somboon & Thiramongkol, 1992; Horton et al., 2005; Bird et al., 2010; Li et al., 2012; Hutangkura, 2014; Surakiatchai et al., 2018) (Figure 3, 4 and 5). However, the timing of the mid-Holocene high stand has been under-debated. Hutangkura (2014), for example, reconstructed the sea level in Chao Phraya Plain, Thailand, regarding pollen records and suggested the highstand at 8.4 cal ka BP. However, the dating of the peat layer by Somboon and Thiramongkol (1992) indicated a highstand of around 7.3–6.0 ka BP, which is consistent with those from Singapore by Tjia (1996) and Bird et al. (2010). Meanwhile, Horton et al. (2005) suggest that the sea level high stand was at 4.8–4.4 cal ka BP. The discrepancies can be explained by the lack of high-resolution radiocarbon dating (Chabangborn et al., 2020). Alternatively, the inconsistencies are possibly caused by the different responding times of proxies on the environmental shift (Wohlfarth et al., 2012). Otherwise, the sea levels in the Gulf of Thailand were not straightforward, with either gradual rise or fall, but they are punctuated by several time intervals of abrupt changes.

In the late Holocene, the sea level has been gradually fallen from the mid-Holocene high stand (Horton et al., 2005; Zong, 2013; Surakiatchai et al., 2018) (Figure 5). However, the record of the Malay-Thai Peninsular (Tjia, 1996) and evidence of the coastal area of Thailand (Sinsakul, 1992) suggest a fluctuating sea level after mid

Holocene high stand at 5.0-6.0 ka BP (Figure 6). Moreover, a recent study of pollen records from Sam Roi Yot wetland on the west coast of the Gulf of Thailand also suggests sea level fluctuation after high stand, significant regression occurred at 2.9 and 1.8-1.4 cal ka BP, sea level again raised at 1.4-1.0 cal ka BP before declining hereafter (Jirapinyakul et al., 2023). These arguments of the Late Holocene sea level are still under debate therefore further studies in detail are needed.

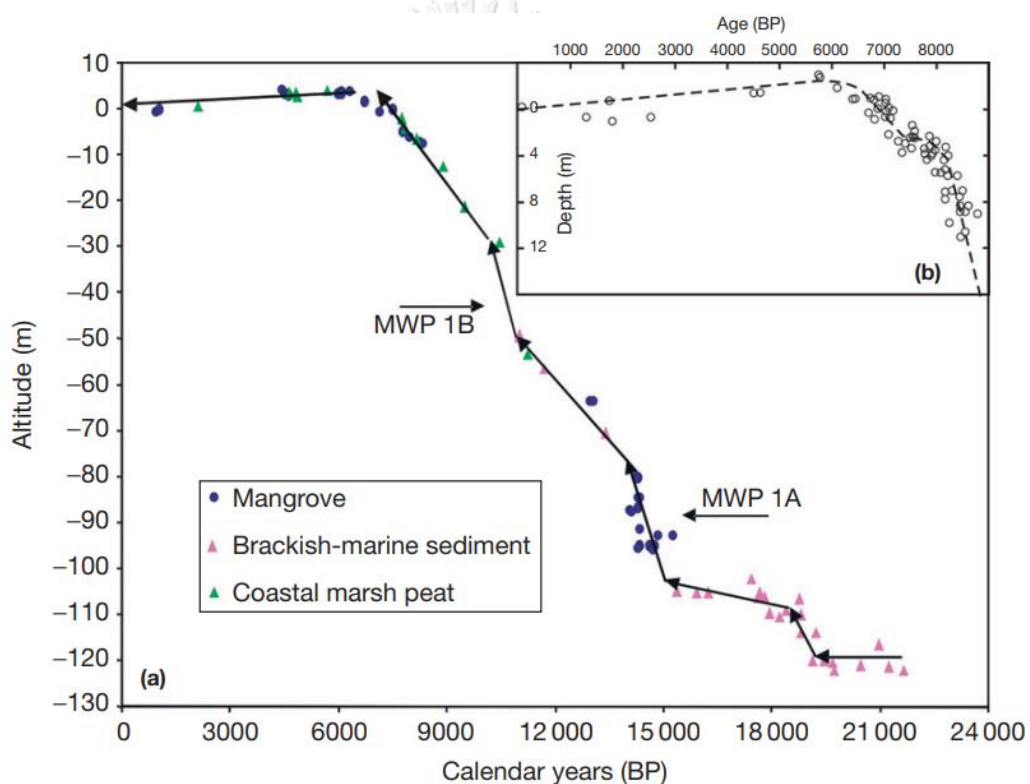

Figure 1 A relative sea-level curve (a) based on sea-level index points compiled from the Bonaparte Gulf, north Australia (Yokoyama et al., 2000), the Sunda Shelf (Hanebuth et al., 2000), and the Strait of Malacca (Geyh et al., 1979). A new record (b) from Singapore (Bird et al., 2010) shows that sea-level rise slowed down around 8000 years BP and accelerated around 7500 years BP (Zong, 2013).

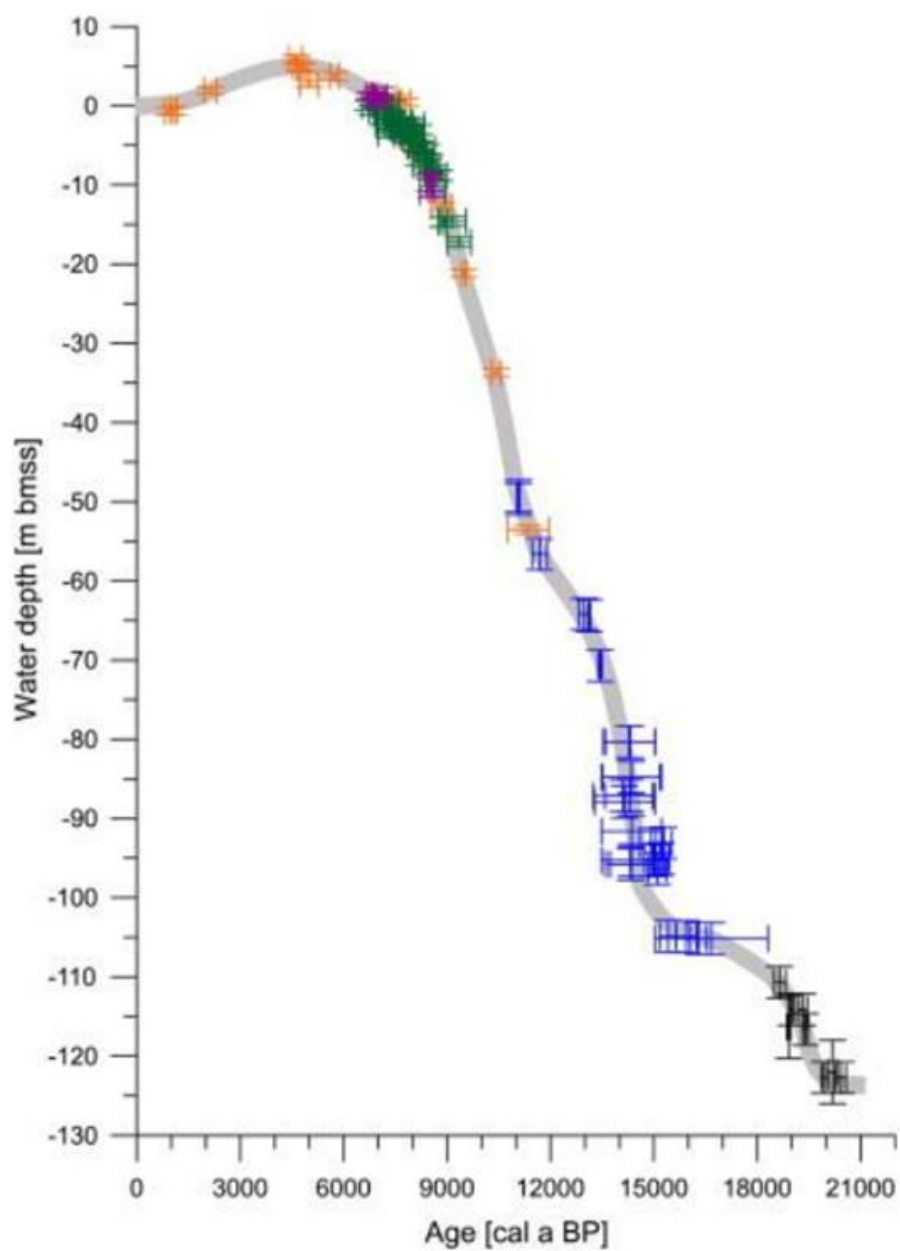

Figure 2 Reconstruction of sea level history for the past 21 ka showing all data recently available from the Sunda core region. Data compiled from Geyh et al. (1979) (orange; Strait of Malacca), Hesp et al. (1998) (purple; Singapore), and Hanebuth et al. (2009) (black; Sunda Shelf) (Hanebuth et al., 2011).

2.3 Study area

The study area is an open pit ($13^{\circ} 32.145'N$ to $13^{\circ} 32.155'N$ and $100^{\circ} 21.684'E$ to $100^{\circ} 21.725'E$) located 5 km west of the Phanthai Norasing subdistrict administrative organization office, Samut Sakhon Province, Thailand, and approximately 4.8 km north of the upper Gulf of Thailand (Figure 7). The open pit is approximately 25.48 m depth below the surface, covering approximately 0.42 km^2 . Sediment samples were taken from 25.48 – 7.2 m depth below the surface. The profile above 7.2 m below the surface was not here including because of soil slump and possible disturbed by the pit construction. The environment surrounding the open pit was mostly occupied by community and shrimp farms (Figure 8). *Suaeda maritima* was a plant that was mostly found near the open pit.

Whereas *Rhizophora sp.* and *Nypa fruticans* were found in a tidal creek surrounding the study site.

Samut Sakhon Province is located in the lower central plain of Thailand, north of the upper Gulf of Thailand. The average elevation of this area is 2 m above the present mean sea level (Sinsakul, 2000). The lower central plain deposits were a complex sequence of alluvial, fluvial, and deltaic sediments of Mae Klong, Tha Chin, Chao Phraya, and Bank Pakong rivers (Tanabe et al., 2003). According to the general geological information, the lower central plain is overlaid on more than 2000 m thick of Tertiary and Quaternary sediments. The western and eastern plain margins are associated with alluvial fans and terraces (Sinsakul, 2000) (Figure 9). The geomorphology of the lower central plain system consists of delta plain, tidal flat (mud flat), river mouth flat, delta front, and delta (Tanabe et al., 2003).

The Asian monsoon plays a key role in the climate in Thailand (Chabangborn et al., 2020). The southwest monsoon brings humid air masses from the Indian Ocean and increased precipitation from mid-May to October. The northeast monsoon prevails, leading to cool and dry conditions between October and February. In February and early May, Thailand is under the influence of southerly and southeasterly winds, increasing temperature. The mean annual precipitation in Samut Sakhom is 1200-1400 mm (Thai Meteorological Department, 2022). The highest rainfall is in September, which is 200-300 mm. The mean annual temperature is 28-30 °C (Thai Meteorological Department, 2022).

CHAPTER 3

METHODOLOGY

3.1 Sample collection

Sediment samples were collected from an open pit in Samut Sakhon Province by hammering the 2 cm diameter and 5 cm long PVC tubes in the sediment layers (Figure 10). Sediment samples were taken every 10 centimeters from each soil layer at the bottom of the pond until the top of the site (Figure 11). Discontinuity of soil profile in the pond was insufficient therefore collecting samples must be taken from 4 zones including zones 1, 2, 3, and 4 around the pond to complete all soil profiles. Where zone 1 (Z1) includes sediment from 25.48-19.74 m DBS in unit A-D, zone 2 (Z2) includes sediment from 19.67-17.37 m DBS in the top of unit D to unit E, zone 3 (Z3) includes sediment from 14.93-14.29 in unit F-G, and zone 4 (Z4) includes sediment from 14.26-7.20 in unit H-I. The sediment samples were placed in PVC tubes, transported to the Department of Geology, Chulalongkorn University, and kept for further analysis. The laboratory work included a detailed lithostratigraphic description of the sediment sequences, X-ray fluorescence, pollen analysis, loss on ignition, and radiocarbon dating.

Level measurement was measured by using an Automatic level where the reference level was approximately the same level as Samut Sakhon Rural Road 2004. The open pit is around 18.28 m thick with the level of the bottom 25.48 and the top 7.20 m. The unit of m depth below the surface (m DBS) was used in this study where the surface means the Samut Sakhon Rural Road 2004 level.

3.2.1 X-Ray fluorescence

The consecutive 10 cm sediment samples were dried at 105°C for 12 hours for XRF analysis. The dried samples were ground in order to be homogeneous. Subsequently, sediment samples were put into a plastic crucible (Figure 12), and measured chemical compositions by using the handheld X-ray Fluorescence (XRF) model Olympus Vanta XRF series to assess the relative variabilities of each element (Figure 13). The concentrations of 39 elements (i.e., P, S, Cl, K, Ca, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Rb, Sr, Y, Zr, Nb, Mo, Ag, Cd, Sn, Sb, Ba, La, Ce, Pr, Nd, Ta, W, Au, Hg, Pb, Bi, Th, and U) were detected by the handheld XRF. However, the concentrations of P, Cr, Co, Se, Mo, Ag, Cd, Sn, Sb, La, Ce, Pr, Nd, Ta, W, Au, Hg, Bi, Th, and U did not reach the instrumental detection limit and excluded for the further analysis.

Figure 12 (a) Sediment sample in plastic crucible for XRF measurement, (b) handheld X-ray fluorescence analyzer model Olympus Vanta XRF series.

3.2.2 Loss on ignition (LOI)

The consecutive 10 cm samples were prepared for the LOI followed the procedure of Heiri et al., (2001). Crucibles and approximately 3 cm³ of sediment samples were weighed and then dried at 105°C for 12 hours. Subsequently, the dried samples were combusted at 550°C for 6 hours (Figure 14).

Calculation of the relative organic carbon content can be estimated by the percentage of weight loss at 550°C following the equation (1).

$$LOI_{550} = \frac{DW_{105} - DW_{550}}{DW_{105}} \times 100$$

(1)

Where LOI_t = weight loss on ignition at t °C (g)

DW_t = dry weight of samples at t °C (g)

Then, the samples were combusted at 950°C for 3 hours in order to eliminate carbonate content in the form of CO_2 . The weight loss at 950°C can be calculated following equation (2).

$$LOI_{950} = \frac{DW_{550} - DW_{950}}{DW_{105}} \times 100$$

(2)

Combustion at 950°C (3), in order to transfer $CaCO_3$ in the sample into CO_2 and CaO . CO_2 is the weight loss. Consequently, the weight loss at 950°C was multiplied by 2.27 in order to assess the carbonate content ($CaCO_3$) (3).

$$\frac{CaCO_3}{CO_2} = \frac{MW_{CaCO_3}}{MW_{CO_2}} = \frac{100.086 \text{ g/mol}}{44.009 \text{ g/mol}} = 2.27$$

(3)

Where MW = Molecular weight (g/mol)

Figure 13 Crucible in a furnace for Loss on ignition analysis.

CHULALONGKORN UNIVERSITY

3.2.3 Grain Size Analysis

Seventy-three samples for the grain size analysis were prepared for each consecutive 10 cm depth following Rowell (2014).

3.2.3.1 Pretreated samples

Each subsample was treated by 20 ml of 10% (v/v) HCl, 20 ml of 10 %, and 30% H_2O_2 in order to eliminate carbonate and organic contents, respectively (Figure 14). The prepared samples were cleaned by deionized water 3 times and dried in an oven for 12 hours. Dried sediment samples were ground to break up the sediment into a smaller size.

The samples were eventually analyzed for the grain size distribution by laser diffraction technique by Horiba model Partica LA-960V2 Laser Scattering Particle Size Distribution Analyzer at the Department of Marine, Faculty of Science, Chulalongkorn University (Figure 14).

The grain size distribution was calculated to mean size particle by the following equation (5).

$$D[4,3] = \frac{\sum_i^n D_i^4 v_i}{\sum_i^n D_i^3 v_i} \quad (5)$$

Where

$D [4,3]$ = the mean diameter over volume

D_i = mean of dacile i

v_i = dacile i

Figure 14 (a) The process of pretreating sediment sample with H_2O_2 to eliminate organic content, (b) Horiba model Partica LA-960V2 Laser Scattering Particle Size Distribution Analyzer.

3.2.4 Pollen analysis

Sixty sediment samples were prepared based on Ellison (2008). Subsamples from the bottom, middle, and top of each sediment layer were selected for pollen analysis.

3.2.4.1 Samples digestion

Subsamples were taken about 1 cm³, treated by 10 ml of 10% KOH, and heated on a hotplate to disperse the sediment (Figure 15). Subsamples were subsequently sieved with a mesh size of 0.2 mm (Figure 15). The sieve remains were washed by deionized water multiple times

For the Acetolysis method, subsamples were treated by glacial acetic (CH₃COOH), and mixed acetic anhydride (CH₃CO₂O) and 96% sulfuric acid (H₂SO₄).

3.2.4.2 Heavy Liquid

Heavy liquid, Sodium polytungstate (3Na₂WO₄ • 9WO₃ • H₂O) which density is 2.0 g/cm³, was added into subsamples, and water was added, respectively. The prepared samples were centrifuged at the speed of 2000 rpm for 2 minutes. Consequently, the heavy liquid with pollen was separated from the solvent by using a dropper. The samples were washed by 95% alcohol, added silicone oil then dried at 60 °C for 12 hours to eliminate alcohol.

Eventually, the samples were mounted on glass slides using Paraffin and pollens were identified under stereomicroscope based on their morphology including aperture, sculpture, and size (Figure 15). Pollens were identified in regard to Punwong (2007).

Figure 15 The process of preparing the sample for pollen sample analysis, (a) sediment samples digestion by KOH and heat with a hot plate, (b) sample sieving sample through 0.2 mm mesh, (c) pollen samples mouthed on glass slides using Paraffin.

3.2.5 Radiocarbon dating

Radiocarbon dating in this study has focused on bulk sediment and shells. Bulk sediment samples were dried at 110°C for 12 hours and then let it cool down. Dried bulk sediment was ground into a smaller size, pack into aluminum foil. Shell samples were picked up by forceps and cleaned with deionized water multiple times. Shell samples were dried at 60°C for 12 hours (Figure 16). The dating samples were packed into aluminum foil and then prepared samples were sent to analyze by using the Accelerated Mass Spectrometer (AMS) at direct AMS, the USA (Figure 16).

The radiocarbon dating results from bulk sediment were calibrated by using a calibration curve of InCal20 (Plicht et al., 2020) while shells were calibrated by MARINE20

with -174 Marine error and 70 uncertainty (Southorn et al., 2002). The age-depth model was constructed for CP-4 by interpolation between the adjacent dating results.

Figure 16 (a) Shell sample for radiocarbon dating after being cleaned by deionized water and dry, (b) bulk sediment sample in foil package prepared for sent to dating.

CHAPTER 4

RESULTS

4.1 Stratigraphic Description of Samut Sakhon Site

The sedimentary sequence from the open pit is approximately 18.3 m thick, extending from 25.48 to 7.20 m DBS. According to the sedimentary description during the field survey, this sequence can be divided into 9 units, i.e., units A to I from the bottom to top, consisting of 14 layers (Table 4).

Unit A

Unit A is well-compacted light grey clay with a paucity of organic matter. This unit is laid down at the lowermost part of the sedimentary sequences. It extends below approximately 24.70 m DBS. The obvious high silt fraction can be observed in the upper part of this unit before gradual transfers to unit B (Table 4 and Figure 17).

Figure 17 The well compaction light grey clay of unit A.

Unit B

Unit B is a relatively thin layer of brown clayey silt intervened between the light grey clay of unit A and the oxidized grey clayey silt of unit C. It is approximately 0.38 m thick and extends between 24.70 and 24.32 m DBS (Table 4 and Figure 28).

Figure 18 The brown silty clay of Unit B.

Unit C

Unit C consists of oxidized grey clayey silt (layer 3) and grey clayey silt with more clay content layer (layer 4). The purple color of these sediments is possibly caused by oxidation. This unit is approximately 1 m thick and can be found at 24.32-23.38 m DBS (Table 4 and Figure 19).

Figure 19 The grey clayey silt with purple oxidized surface of unit C.

Unit D

Unit C is overlaid by unit D, which is interbedded between the brown clayey silt layers (Table 4 and Figure 20). Unit D can be divided into 5 layers, i.e., layers 5-9 from the bottom to top. This unit is approximately 4.4 m thick and extends from 23.38-19.00 m DBS. It is punctuated by a layer of clayey silt with gravel (approximately 10-15%) at 19.70-19.50 m DBS. Regarding the XRD analysis at the Department of Geology, Chulalongkorn University, the gravel is entirely composed of SiO_2 , and CaCO_3 , indicating the caliche layer

(Alptekin & Hatipoglu, 2018) (Figure 21). The limestone mountain is not available in the study area and vicinity area. In addition, CaCO_3 is a low concentration in the sediments from Tha Chin and Chao Phraya Rivers (Hassain et al., 2017). Since shells and shell fragments are abundant in the upper part of the sediment sequence, the precipitated CaCO_3 gravel is possibly caused by infiltration of hardwater dissolved from the upper shell layer.

Figure 20 The interbedded between the brown clayey silt of unit D.

Figure 21 Sediment in unit D and a presence Caliche layer.

Unit E

Sediment in Unit E is laminated light grey clay, which is approximately 19.00–17.37 m DBS. The sediments in this layer are characterized by hard and well compaction, making it difficult to mound by PVC pipe (Table 4 and Figure 22).

The upper part of unit E is a road for transportation in the open pit close to the slump sediments. To avoid contamination by younger sediments, the sampling site was moved to approximately 500 m to the west, making the loss of information approximately 2.5 m thick.

Figure 22 The laminated light grey clay of unit E.

Unit F

The sediments in unit F are purple clay, which is possibly oxidized. This unit can be found at approximately 14.70 m DBS (Table 4 and Figure 23).

Unit G

The purple clay in unit F gradually transfers to the greenish-dark grey clay of unit G. It is approximately 0.22 m thick at 14.70–13.33 m DBS. In unit G, shells and shell fragments can be found in the sediments (Figure 23). The shells and shell fragments increase by 5-10% from the bottom to the top of this unit (Table 4).

Unit H

Unit G is gradually changed to the dark grey clay of unit H. The shells and shell fragments are approximately 5% in this unit (Figure 24 and 25). Unit H is 0.67 m thick, approximately 13.33–12.66 m DBS (Table 4).

Figure 23 The boundary between the greenish-dark grey clay of unit G and the dark grey clay of unit H.

Unit I

Unit I is the uppermost unit of the sedimentary sequences. This unit is relatively thicker than the other units, which is at least 5.46 m thick. It is composed of dark brown clayey silt. Shells and shell fragments are abundant in the middle of unit I, approximately more than 15%. Unit I extends from 12.66 to 7.20 m DBS (Table 4 and Figure 24, 25). Summary of the sedimentary sequence in Samut Sakhon show in Figure. 26.

Figure 24 The dark brown clayey silt in unit I.

Figure 26 Lithostratigraphic column of sediment sequence of the open pit at Samut Sakhon.

4.2 Loss on ignition (LOI)

The consecutive 10 cm depth of sediment samples were combusted at 550°C (LOI550) and 950°C (LOI950) to achieve the qualitative changes in organic and carbonate content.

The LOI550 is approximately 7.5% in units A and B (Figure 27). It abruptly decreases to 5% at the boundary between units B and C before gradually increasing to 7.5% at 22.00 m DBS (the lower part of unit D) (Figure 27). The LOI550 suddenly declines and reaches 2.5% at 22.00-21.00 m DBS (Figure 27). It is a slight change of 2.5% from 21.00 m DBS to the upper part of unit D (Figure 27). The LOI550 abruptly increases to 10% in unit E. In units F to I, the LOI550 generally increases from 10 to 20% (Figure 27).

The LOI950 varies from 2.5% to 5% (Figure 27). The variation of the LOI950 is approximately analogous to that of the LOI550, except for units B to D (Figure 27). The LOI950 gradually decreases from 2.5% to 1% in units B to D (Figure 27). In addition, the LOI950 significantly increases and reaches its maximum of 12.5% in the caliche layer (Figure 27).

Figure 27 Comparison of lithostratigraphy (left), and profile of LOI550 (middle) and LOI950 (right) of sediment sequence of the open pit at Samut Sakhon.

4.3 Grain size analysis

The sediment sequence of the open pit at Samut Sakhon is generally composed of a silt fraction of 75%, 20% sand, and 5% clay (Figure 28).

In units A to the lower part of unit D (24.70-22.16 m DBS), the silt fraction is approximately 75% and the most predominant constitution. Sand component is 5% in units A and B, suddenly increases and reaches 40% in unit C, and varies from 20% to 40% in the lower part of unit D (24.13-22.16 m DBS) (Figure 28). In contrast, the clay fraction is 25% in units A and B, abruptly declines to less than 5% in the boundary between units B and C, and slightly increases to 15% in units B and the lower part of unit D (25.28-22.16 m DBS) (Figure 28).

The sand fraction suddenly increases and reaches 80%, while silt and clay components decrease by 75-20% and 20-5%, respectively, from 22.10 to 20.84 m DBS (Figure 28). The sedimentary components are a slight change of 80% sand, 20% silt, and less than 5% clay from 20.74 to 18.97 m DBS. The decrease in sand fraction consists of an increase in silt and clay components at 18.57-17.37 m DBS, before slight changes of 5% sand, 70% silt, and 25% clay in unit E (Figure 28).

Sand fraction increases from 10% to 20% in unit F, reaches 40% in unit G, decreases to 5% in units G and H, and gradually enhances by 5 to 40% in unit I. In units F to I, the silt component is generally 80%, except for 8.50 m DBS, which declines to 60%. The clay constituent is generally less than 5%, except for 14.00 and 11.50 m DBS, where it abruptly increases to 25% (Figure 28).

The volumetric mean diameter ($D[4,3]$) is less than 5 μm in units A and B. It slightly increases to 50 μm in unit C before declining to 10 μm in the lower part of unit D (23.50-22.16 m DBS) (Figure 28). In unit D, the volumetric mean diameter significantly increases and reaches its maximum of 200 μm at 20.74-18.97 m DBS (Figure 28). The volumetric

mean diameter suddenly declines to resemble those in units A and B. In units F to I, the volumetric mean diameter gradually increases from 20 to 40 μm (Figure 28).

Figure 28 The lithostratigraphic column and percentage of sand, silt, and clay components, and volume metric mean grain size of the sediment sequence of the open pit at Samut Sakhon.

4.4 X-ray Fluorescence (XRF)

According to the XRF analysis, 39 elements of P, S, Cl, K, Ca, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Rb, Sr, Y, Zr, Nb, Mo, Ag, Cd, Sn, Sb, Ba, La, Ce, Pr, Nd, Ta, W, Au, Hg, Pb, Bi, Th, and U can be detected by the handheld XRF. However, the continuous detectable elements consisting of Fe, Cl, K, Ca, S, Ti, Mn, Ba, Zr, Sr, Rb, and Zn are included in the further analysis (Figure 29).

The Fe, K, Ti, Zr, Rb, and Zn concentrations demonstrate the analogous pattern of variation. There are high concentrations of 26000, 13000, 3800, 400, 130, and 50 ppm (Figure 29) of Fe, K, Ti, Zr, Rb, and Zn, respectively, in units A to the lower part of unit D (23.50-22.16 m DBS). Fe, K, Ti, Zr, Rb, and Zn decreased to approximately 21000, 9000, 1200, 130, 90, and 20 ppm, respectively, at 20.74-18.97 m DBS (Figure 29). In unit E, they increase and approximately resemble those of unit A to the lower part of unit D. Fe, K, Ti, Zr, Rb, and Zn concentrations are insignificant changes of 27000, 10000, 2900, 350, 100, and 40 ppm, respectively, in units F to I (Figure 29).

Cl, Ca, and S concentrations in units A to E are 8000, 1200, and 200 ppm, respectively (Figure 29). They are significantly lower than those in units F to I, which are approximately 8000- 80000 ppm of Cl, 2900-30000 ppm of Ca, and 2200-30000 ppm of S (Figure 29). The exception is in the caliche layer, in which the Ca concentration significantly increases and reaches 140000 ppm (Figure 29).

Ba concentration is insignificant changes and varies from 200 ppm to 600 ppm. Mn concentration is relatively low, except at 20.74-18.97 m DBS, where it varies from 40 ppm to 18000 ppm (Figure 29). Sr concentration significantly changes from 90-200 ppm at 20.74-18.97 m DBS, and relatively increased 40-250 ppm from unit F-I (Figure 29).

The Principle Component Analysis (PCA) was used to assess the relationship between each element. The Kaiser Meyer Olkin test (KMO) was 0.623, indicating an adequacy of PCA analysis. The eigenvalues were 4.5 and 2.3 on components 1 and 2,

respectively, and the cumulative variance was 57.5% (Table 5). Therefore, the components 1 and 2 are selected in this study. The first principal component was ~37.9% of the total variance (Figure 30). It consists of K, Ti, Fe, Rb, and Zn (Table 6). The second principal component is ~19.6% of the total variance, consisting of S, Cl, Sr and Ca, opposing to Ba (Table 6 and Figure 30).

The elemental ratios are often applied for paleoclimatic and paleoceanographic reconstructions (e.g., Clift et al., 2014; Kylander et al., 2011). Among these ratios, Ti/Ca and Zr/Rb were proxies to assess terrigenous input and its intensity (Kylander et al., 2011; Hou et al., 2020; Mesa-Fernández et al., 2022). Titanium is normally delivered by terrigenous input, i.e., fluvial and eolian transportation (Hou et al., 2020), while calcium is originated by marine biogenic carbonate (Mesa-Fernández et al., 2022). Rubidium is common in mica and clay minerals (Kylander et al., 2011). Their strong absorption to clay minerals of Rubidium makes it immobile in the environment. Zirconium is generally found as zircon and enriched in silt (Kylander et al., 2011)

Zr/Rb ratio value is abruptly increased from 3 to 4.5 at the boundary between units B and C (approximately 24.32 m DBS) (Figure 31). The ratio gradually declines to 3 at the top of unit E, from 24.32 to 17.37 m DBS. Zr/Rb ratio is approximately 5 and varies from 3 to 5 in units F to the lower part of unit I (14.70–12.66 m DBS). It gradually decreases from 4 to 2.5 in the upper part of unit I (11.80–7.20 m DBS) (Figure 31).

Ti/Ca is a slight change of 16 at 24.32 m DBS before abruptly declining to 0.5 between 24.50 and 21.00 m DBS (Figure 31). The ratio gradually increases and reaches its maximum of 20 at 19.00–17.37 m DBS. The Ti/Ca is an insignificant change in units F to I (Figure 31).

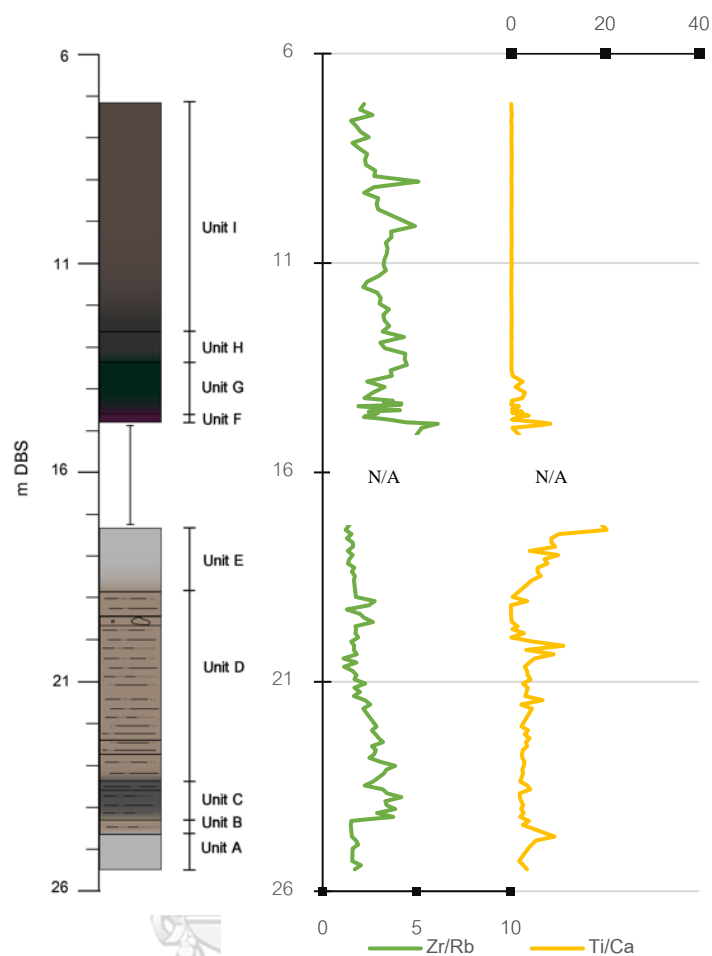

Figure 31 The lithostratigraphic column and variations of Zr/Rb and Ti/Ca ratios of the sediment sequence of the open pit at Samut Sakhon.

4.5 Palynology

Thirty-four pollen taxa can be found in the sediment samples obtained from the pit, divided into 4 assemblages: mangroves, back mangroves, non-mangroves taxa, and unidentified taxa following Santisuk (1983) and Punwong (2007) (Table 7). According to the pollen analysis, the sedimentary sequence can be divided into two main pollen zones, i.e., A and B from the bottom to the top.

Table 7 Pollen assemblage of the sediment sequence of the open pit at Samut Sakhon.

Assemblage	Assemblage name	Plant assemblage
1	mangroves	<i>Avicennia</i> , <i>Bruguiera</i> , <i>Lumnitzera</i> , <i>Rhizophora</i> , and <i>Sonneratia</i>
2	Back mangroves	<i>Acanthus</i> , <i>Acrostichum</i> , <i>Combretaceae</i> , <i>Oncosperma</i> , <i>Pandanus</i> , <i>Suaeda</i> , <i>Stenochlaena</i> , and <i>Xylocarpus</i>
3	Non-mangrove taxa	<i>Altingia</i> , <i>Amaranthaceae</i> , <i>Anacardiaceae</i> , <i>Araceae</i> , <i>Clerodendrum</i> , <i>Casuarina</i> , <i>Cyperaceae</i> , <i>Dipterocarpaceae</i> , <i>Fagaceae</i> , <i>Lagerstroemia</i> , <i>Magnoliaceae</i> , <i>Myrsinaceae</i> , <i>Myrtaceae</i> , <i>Pinus</i> , <i>Poaceae</i> , <i>Quercus</i> , <i>Sapindaceae</i> , <i>Ceratopteris</i> , <i>Davillia</i> , <i>Gleicheniaceae</i> , and <i>Pteris</i>
4	Unidentified	-

4.5.1 Pollen zone A (25.48-17.37 m DBS)

The pollen is meager in the pollen zone A, which varies between 2 to 17 pollen grains. Pollens of non-mangrove herb, Amaranthaceae and Poaceae were found in unit A. In unit C, Amaranthaceae pollen significantly increased and reached its maximum of 17 pollen grains. In the middle of unit D, pollen grains are hardly found (< 2 grains and 1 pollen taxon) therefore this interval is defined as the barren zones of pollen. The pollens of *Bruguiera* -landward mangrove plant- and Poaceae are found in unit D. In unit E, two Poaceae pollens are present.

4.5.2 Pollen zone B (14.89 – 7.20 m DBS)

Pollen zone B can be further divided into 4 pollen zones (Figure 32).

4.5.2.1 Pollen zone B1 (14.89-14.70 m DBS)

Pollen zone B1 corresponds to sedimentary unit F. Pollen is abundant in the upper part of pollen zone B1, especially *Acrostichum*, back mangrove pollen taxa, which found 6 grains and reaches 30% (Figure 32). In addition, mangrove pollen taxa, including *Bruguiera*, *Stenochlaena*, *Rhizophora*, and *Sonneratia*, are found in 1, 1, 2, and 5 grains which are 5%, 5%, 10%, and 25%, respectively (Figure 32). Cyperaceae, Poaceae, and Monolete, the non-mangrove pollen taxa, are presented 1-2 grains which are around 5-10% (Figure 32).

4.5.2.2 Pollen zone B2 (14.70-12.66 m DBS)

Pollen zone B2 corresponds to sedimentary units G and H. The mangrove pollen taxa, especially *Bruguiera* and *Rhizophora*, *Sonneratia* are more abundant than those of the previous pollen zone. However, the percentages of *Bruguiera* and *Rhizophora* decreased by 30-2% and 70-2% from pollen grains of 140 to 1 and 150 to 1, respectively, from the bottom to the top of pollen zone B2. (Figure 32). In contrast, the back-mangrove pollen taxa of *Acrostichum* increased by 2-

39 grains which is 10-40% from the bottom to the top of this pollen zone (Figure 32). Cyperaceae and Poaceae are around 20% at 13.56-13.3 m DBS (Figure 32).

4.5.2.3 Pollen zone B3 (12.60-11.90 m DBS)

Pollen zone B3 corresponds to the lower part of sediment in unit I. *Rhizophora*, mangrove pollen taxa, decreases to 15% which is 5 grains (Figure 32). The back-mangrove pollen taxa of *Acrostichum* became predominant, which is 3-25 grains, around 70-75%. Cyperaceae pollen taxa are found in 5 grains which is 5% at the boundary between pollen zone B2 and B3 (Figure 32).

4.5.2.4 Pollen zone B4 (11.90-7.20 m DBS)

Pollen zone B4 corresponds to sedimentary units I above 11.90 m DBS. This pollen zone found a variety of pollen taxa. Mangrove pollen taxa of *Bruguiera* and *Rhizophora* have been found in 1-16, and 1-88 grains which are around 10-20% and 20-30%, respectively (Figure 32). Back-mangrove pollen taxon of *Acrostichum* significantly decreases compared to the previous zone and continuously declines from 15 to 10% in the pollen zone B4. The non-mangrove pollen taxa have become prevailing (Figure 32). Cyperaceae pollen varies from 3-35 which decreases by 40-20 %, while Poaceae pollen increases 7-83 grains by 15-60% from the bottom to the top of pollen zone B4 (Figure 32).

4.6 Chronology

The chronology of sedimentary succession is based on sequential radiocarbon dating of bulk sediment and marine shells (Table 8). The dating results obtained from the samples in sedimentary units A to E are constrained to the late Pleistocene (Table 8). However, the results derived from the samples in sedimentary units F to I are limited to the mid/late Holocene (Table 8). This abrupt change in dating results indicates a possible

unconformity between 18.47 and 14.89 m DBS. Therefore, further analysis is separated into the sections from 25.48 to 18.47 m DBS and from 14.89 to 7.54 m DBS.

The chronology of the lower part of the sedimentary succession (from 25.48 to 18.47 m DBS) relied on the sequential radiocarbon dates of bulk sediments. The dating results obtained from sample no. #10, #9, and #7 are significantly inconsistent with those from the adjacent depth (Table 8). They are excluded from further analysis since the contamination of older or younger origins of organic material in the bulk sediment frequently exceeds the depositional timeframe (Grimm et al., 2009). Consequently, the age-depth model for section 25.48-18.47 m DBS is based on interpolating the dating results from sample no. #11, #8, and #6, extending from 26500 to 22650 cal years BP (Figure 33). The sedimentation rate is c. 0.1 cm/year at c. 25.48-22.06 m DBS, and significant increases to 1.5 cm/yr at c. 22.06-18.47 m DBS (Figure 33).

In the upper part of the sedimentary succession (from 14.89 to 7.54 cm DBS), the chronology extends from 5400 to 1064 cal years BP. In addition, since it was shell samples the calibration will be used of the MARINE20 curve instead. However, the dating results obtained from sample no. #2 does not fit this general pattern and resulted in an older age than expected. This older age is possibly caused by reworking and excluded from the age-depth model constructed by Bacon. The deposition rate is approximately 0.11 cm/year from 13.77 to 14.88 m DBS, 0.92 cm/year from 13.76-11.66 m DBS, and 0.14 cm/year from 11.65-7.20 m DBS hereafter (Figure 34).

Table 8 14C dated from bulk sediment and shell samples for Samut Sakhon site.

Sample no.	m DBS	Material	14C age (BP \pm σ)	Cal year BP	Unit
#1	7.54	Shell	1672 \pm 24	1,239	I
#2	9.88	Shell	4565 \pm 30	4,791	I
#3	11.66	Shell	4070 \pm 28	4,156	I
#4	13.78	Shell	4245 \pm 29	4,385	G

CHAPTER 5

DISCUSSION

Regarding sequential radiocarbon dating, the sedimentary sequence at the open pit at Samut Sakhon can be divided into the late Pleistocene approximately 26.5-22.6 cal ka BP and the mid/late Holocene deposits approximately 5.4-1.1 cal ka BP.

5.1 Environmental reconstruction during the late Pleistocene

The radiocarbon dating obtained from sample no. #11, #8, and #6 demonstrated that the sedimentary section was deposited at 26.5-22.7 cal ka BP, which was contemporary with the Last Glacial Maximum (LGM: 25-19 cal ka BP) (e.g., Negri, 2012; Puchala et al., 2011; Gorbarenko et al., 2022) (Table 8). The sea level lowstand during the LGM exposed the Sunda shelf connected the Southeast Asian Mainland to the Indonesian archipelago (e.g., Sathiamurthy & Voris, 2006; Puchala et al., 2011; Rugmai & Grote, 2023). Since, Samut Sakhon was a part of the Sundaland, the sedimentary deposit was potentially controlled by the Tha Chin and Chao Phraya Rivers (Sinsakul, 2000; Tanabe et al., 2003). The reconstructions of the LGM climate generally revealed the strengthening of winter monsoon, making the persistent cooler and drier conditions than present of the Savanna (tropical wet and dry) climate (e.g. van Campo et al., 1982; Huang et al., 1997; Hodell et al., 1998; von Rad et al., 1999; Hope, 2001; Naidu, 2004; Prabhu et al. 2004; White et al., 2004; Tiwari et al., 2006; Ansari and Vink, 2007; Cosford et al., 2010; Fleitmann et al. 2011).

Sedimentary characteristics of this stage include sediment from units A to E that mixed light grey clay and brown/grey clayey silt layer. The paucity of pollen that identifies as a barren zone of pollen is possibly caused by the oxidizing of the study area that agrees with the color of the sediment. These results possibly indicate the temporal exposure of

the study area, which was the floodplain of Tha Chin and Chao Phraya Rivers during the LGM at 26.5-23.0 cal ka BP.

Noticeably, the significant increases in sand fraction and volume metric diameter were consistent with relatively low organic matter, regard to LOI550, and high Ti/Ca value in sedimentary unit D at 21.6-19.1 m DBS. These results obviously suggested an abruptly increased runoff intensity in the study area at 23.0-22.8 cal ka BP (Figure 35).

5.2 Environmental Reconstruction during the mid/late Holocene

In the mid-Holocene, sea level increased and reached its highstand at around 8-4 cal year BP (Somboon & Thiramongkol, 1992; Horton et al., 2005; Bird et al., 2010; Li et al., 2012; Hutangkura, 2014; Surakiatchai et al., 2018). However, the timing of the mid-Holocene highstand has been under debate. For example, the reconstruction of the sea level regarding pollen records in Chao Phraya Plain, Thailand, suggested the highstand at 8.4 cal yr BP (Hutangkura, 2014). However, the dating of the peat layer obtained from the same area indicated a highstand of around 7.3-6 year BP (Somboon & Thiramongkol, 1992) that was contemporary with the dating of peat layer at Singapore by Tjia (1996) and Bird et al. (2010). Whereas, Horton et al. (2005) suggest that the sea level high stand was at 4.85 – 4.45 cal year BP. In the late Holocene, the sea level has been generally considered to be a gradual fall based on various studies associated with the glacial isostatic adjustment (GIA) model (Horton et al., 2005; Zong, 2013; Surakiatchai et al., 2018). However, some records suggest that sea levels have been fluctuating after the mid-Holocene highstand (Sinsakul, 1992; Tjia, 1996; Jirapinyakul et al., 2023). Therefore, the low central plain, including the study area, was directly influenced by the marine processes during the mid/late Holocene.

The radiocarbon dating obtained from sample #5, #4, #3, and #1 indicated that the sedimentary section was deposited at 5.4-1.1 cal ka BP (Table 8). Sedimentary characteristics of the mid/late Holocene stage include sedimentary units F to I. The

presence of high mangrove pollen taxa in greenish-dark grey clay and dark grey clay approximately 14.9-13.7 m DBS is consistent with relatively high organic content, indicating the influence of marine processes (Figure 36). The high pollen accumulation rate that obtained by calculating pollen grains with the rate of deposition suggested the thriving of mangrove forests in the study area at 5.4-4.4 cal ka BP.

The transformation of sediment from greenish-dark grey clay and dark grey clay to dark brown clayey silt is consistent with the decrease in pollen number associated with lower organic matters, referred to the regression at 4.4-4.2 cal ka BP. Moreover, this interpretation is supported by the occupation of the back-mangrove pollen taxa at 13.6-11.7 m DBS (Figure 36). The environment at this time is likely to be a back-mangrove forest.

Non-mangrove pollen taxa became predominant at 4.2–2.3 cal ka BP. The pollen accumulation rate of Cyperaceae and Poaceae which is non-mangrove pollen assemblage indicates that freshwater has more influence in this area. The value of the Zr/Rb ratio, sand fraction, and volume metric mean diameter slightly increased during this time interval referring to higher transportation environment energy. These results suggest the gradual sea level lowering at 4.2–2.3 cal ka BP and the environment in Samut Sakhon seems to be a wetland (Figure 36).

Organic matter and volume metric mean diameter increased at 8.9-7.2 m DBS, demonstrating the higher transportation energy at 2.3-1.1 cal ka BP (Figure 36). Pollen was abundant, especially Poaceae and *Rhizophora*, at this depth. The high pollen accumulation rates of both mangrove and non-mangrove pollen taxa suggested the sea level again increased together with freshwater influence by an occasional increase in runoff at 2.3-1.1 cal ka BP. The environment seems to transfer from a wetland to a brackish water area in this time interval.

5.3 Unconformity of the sedimentary sequence

The sediment in the Late-Pleistocene to Holocene of Chao Phraya delta is known as Bangkok Clay (Sinsakul, 2000; Tanabe et al., 2003). Bangkok clay consists of soft clay from the Holocene and stiff clay from the Late-Pleistocene that unconformably overlaid (Tanabe et al., 2003). Tanabe et al. (2003) suggested the stratigraphy evolution at Tha Chin and Chao Phraya delta plains that shallow marine and fluvial sediment in the Late Pleistocene unconformably overlaid by basal lag sediment with a sharp erosional surface from the mid-Holocene high stand, this erosional surface may occur due to marine transgression or regression.

The sedimentary sequence data from this study is likely to be consistent with Tanabe et al. (2003). The intervals at 17.3-14.9 m DBS in the open pit in Samut Sakhon are possibly divided by the unconformity. The laminate light grey clay layer in unit E indicates deposition during the Late Pleistocene at approximately 22.7 cal ka BP adjacent to the oxidized purple clay layer in unit F indicates deposition during the mid-Holocene at approximately 5.4 cal ka BP.

5.4 Recommendation

The open pit study site was 4 km distance from Phanom Surin Shipwreck in Samut Sakhon Province. Phanom Surin Shipwreck was 2 m depth of the pond edge and 8 km distance from the Gulf of Thailand, the surrounding area was shrimp farms and mangrove plants (The 1st Regional Office of Fine Arts Department, 2016). The dating result indicates an age of approximately 1.1-1.3 cal ka BP (The 1st Regional Office of Fine Arts Department, 2016).

In this study, shell samples were found at 7.5 m depth below the surface (the surface refers to rural road 2004 level) around the open pit indicating an age of 1.2 cal ka BP which is similar to the age of Phanom Surin Shipwreck. These results possibly show that at around 1.3 cal ka BP when the upper Gulf of Thailand was invaded by marine

water. However, the inconsistency in depth between the open pit and shipwreck need to be further studied by the differential global positioning system.

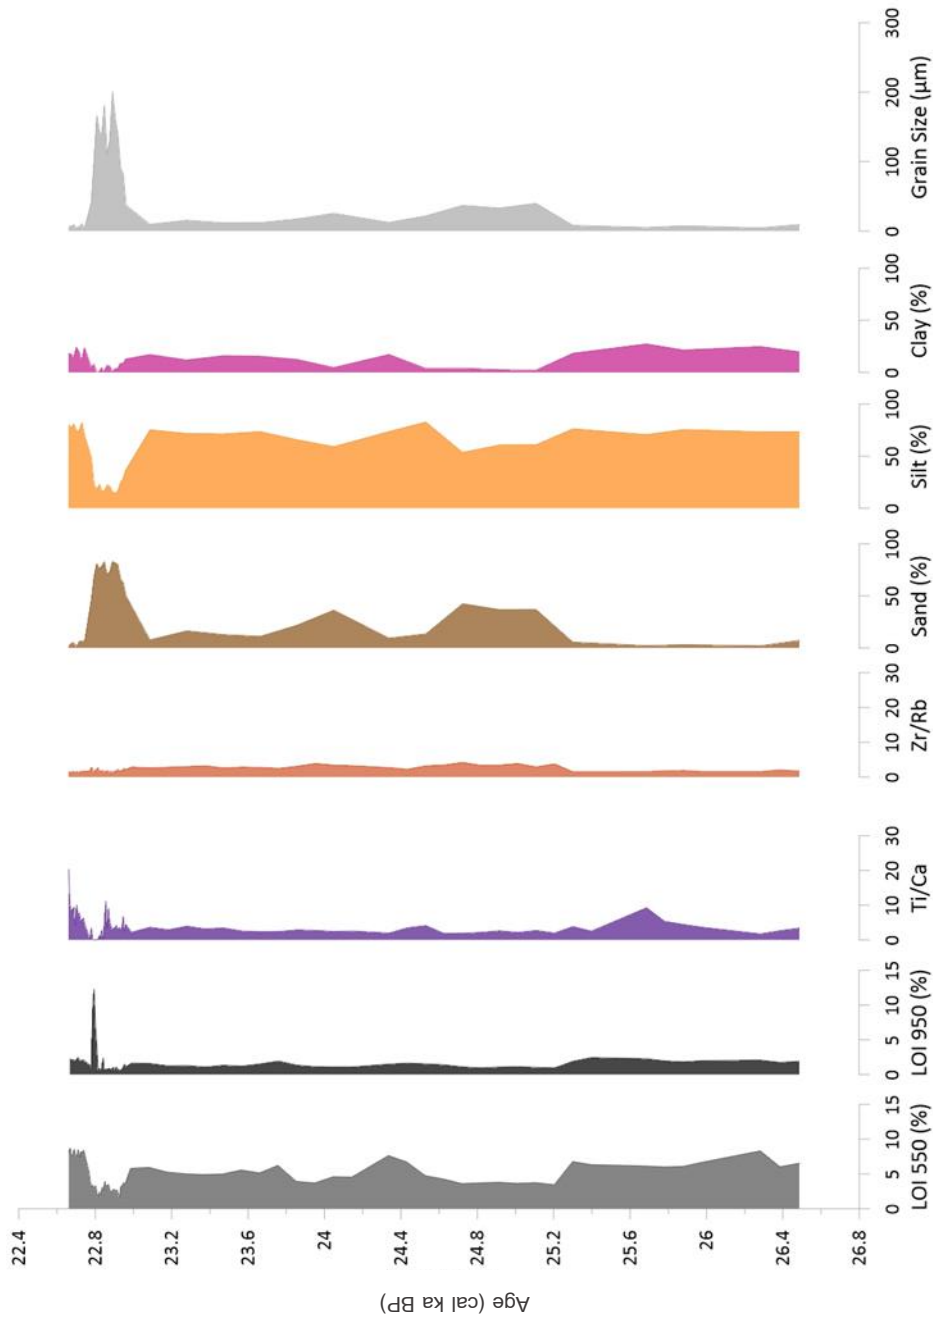

Figure 35 Samut Sakhon evolution in the late Pleistocene according to LOI, Ti/Ca, Zr/Rb, percentage of sand, silt, clay, and grain size.

Figure 36 Samut Sakhon evolution 4 stage in the mid/late Holocene according to LOI, Ti/Ca, Zr/Rb, grain size, and mangrove, back-mangrove, and non-mangrove pollen accumulation rate (PAR).

CHAPTER 6

CONCLUSION AND RECOMENDATION

This study uses LOI, Ti/Ca, and Zr/Rb ratio, grain size, and pollen interpretation together with radiocarbon dating to reconstruct past environments and evolution in Samut Sakhon site, the upper Gulf of Thailand. The past environment in Samut Sakhon site can be divided into two separate parts including the late Pleistocene and the mid/late Holocene.

In the late Pleistocene, the paucity of pollen possibly indicates the temporal exposure of the study area during a dry condition at 26.5-23.0 cal ka BP. Followed by abruptly increased runoff intensity at 23.0-22.8 cal ka BP.

In the mid to late Holocene, the thriving of mangrove forest communities due to sea level transgression happened at 5.4-4.4 cal ka BP. The mangrove forest was transferred to the back-mangrove forest during sea level regression at 4.4-4.2 cal ka BP, and then the sea level continuously decreased until 2.3 cal ka BP. Subsequently, sea level increased in the study area by approximately 2.3-1.1 cal ka BP together with freshwater influence by an occasional increase in runoff.

The sedimentary sequence in Samut Sakhon shows an unconformity at 17.3-14.9 m DBS. The unconformity present between the laminate light grey clay at the Late-Pleistocene and the oxidized purple clay layer at the mid-Holocene.

The correlation between the open pit study site and the Phanom Surin Shipwreck indicates a similar age of around 1.2-1.3 cal ka BP, suggesting that the open pit has been at a deep point deeper than the Phanom Surin Shipwreck during the late Holocene.

The measurement of the depth of the open pit was only conducted by using an Automatic level where Samut Sakhon Rural Road 2004 was a reference level. For further study, level measurement of an Automatic level and measurement of a Differential Global Positioning System where Mean Sea Level was a reference level should be combined to represent the actual level and can be correlated with another study.
