KEYWORD: Rice husk ash, Natural rubber latex, Alginate, crosslinking, Skim natural rubber latex, Fresh natural rubber latex, Bacterial cellulose, Mechanical properties, dielectric properties, Electrical properties

Praewpakun Sintharm : PREPARATION AND CHARACTERIZATION OF RICE HUSK ASH FILLED NATURAL RUBBER FILM: EFFECT OF CROSS-LINKING AGENTS ON MECHANICAL AND ELECTRICAL PROPERTIES .  
Advisor: Prof. MUENDUEN PHISALAPHONG, Ph.D.

Natural rubber (NR) is one of the most important polymers produced by plants and is widely utilized as raw material for many products due to its excellent flexibility. Rice husk ash (RHA) is one of the major agricultural residues generated from the rice milling plant. In order to add value to NR and RHA, this study aims to use different types of RHA (black rice husk ash (BRHA), white rice husk ash (WRHA) and BRHA treated by acid washing (BRHAT)) as filler in NR composites. By the addition of alginate as a thickening and dispersing agent, a maximum of 100 per hundred rubbers (phr) of RHA could be integrated in NR matrix without phase separation. In addition, this study investigated the effects of crosslinking NR composite by  $\text{CaCl}_2$  compared to the common crosslinking process by sulfur vulcanization on mechanical and electrical properties of NR composites. Mechanical properties of the composite films with RHAs in terms of tensile strength, Young's modulus and elongation at break were considerably enhanced, compared to the neat NR film. The composite films reinforced with WRHA demonstrated relatively better mechanical properties than those reinforced with BRHA and BRHAT, respectively. The crosslinking by  $\text{CaCl}_2$  was achieved on NR-WRHA, in which tensile strength and chemical resistance of the composite films were improved close to properties of sulfur vulcanized NR films. The NR composites were biodegradable in soil, with weight loss of 7.6–18.3% of the initial dry weight after 3 months. Dielectric constant, dielectric loss factors and electrical conductivity of the composites were enhanced with RHAs loading. However, dielectric constant, dielectric loss factor and electrical conductivity of NR composites with RHAs had dropped significantly after crosslinking the composites by  $\text{CaCl}_2$  or by sulfur vulcanization. Moreover, bacterial cellulose (BC) reinforced with skim/fresh natural rubber latex (SNRL/FNRL) were future developed by combining the prominent mechanical properties of multilayer BC nanofibrous structural networks and the high elasticity of NR. As compared to FNRL, SNRL could easily diffuse through the pores of a BC network. Many good benefits were obtained for the reinforcement with SNRL, including good mechanical properties, chemical resistance and noticeably improved dielectric properties. The SNRL-BC films are biodegradable and could be mostly or totally decomposed in soil within 6 weeks. The composite films developed in this study display potential for further application as semiconducting polymer films and flexible electronic devices for electronic applications.

## ACKNOWLEDGEMENTS

Firstly, I would like to express appreciation to Prof. Dr. Muenduen Phisalaphong for valuable advice and guidance throughout the entire course of this study. I am extremely grateful to her for her helps to analytical, discussion and suggestions in this work.

This research was funded by the 90th Anniversary of Chulalongkorn University Fund (Ratchadaphiseksomphot Endowment Fund).

I am sincerely thankful to Assoc. Prof. Dr. Sarute Ummartyotin, Prof. Dr. Artiwan Shotipruk, Assist. Dr. Pimporn Ponpesh and Assist. Dr. Suchata Kirdponpattara, the thesis committee member, for giving useful suggestions and critical reviews of my work.

I would like to be thankful to Nakornluang rice milling plant (Phra Nakhon Si Ayutthaya, Thailand), for kindly support to rice husk and rice husk ash which main material in this study. I would like to appreciation to Dr. Adun Nimpaiboon and Rubber Technology Research Centre (RTEC), Faculty of Science, Mahidol University for kindly support to skim and fresh natural rubber latex and advice about natural rubber part in this work.

I would like to special thanks to my family and member of chemical engineering research unit for value adding of bioresources for helpful, suggestion, kindness, friendship, and happiness.

Praewpakun Sintharm

# CHAPTER I

## INTRODUCTION

### 1.1 Motivations

Thailand is the world's largest producer and exporter of natural rubber because the environment of Thailand is highly conducive to rubber tree cultivation. In 2017, over 4.5 million tons of natural rubbers were produced in the country (about 37% of global production) [1]. Rubber is exported in several basic forms including ribbed smoked sheets, concentrated latex and compound rubber. Thailand natural rubber prices have been falling for several years because of oversupply from major rubber producing countries and weak global economy. Therefore, the Thailand government has the policy to increase the value of natural rubber by using a variety of technologies for improving natural rubber properties or transforming natural rubber latex to high value products.

Natural rubber is one of the important elastomers and it is widely utilized to prepare many rubber products such as vehicle tires to belts, condoms, gloves, health equipment and accessories, coatings and floor covering [2]. Natural rubber is non-saturated rubber because its structural unit contains double bond. Natural rubber has very low aging resistance because ozone and oxygen can react with double bond very easily. Therefore, the chemical structure of natural rubber is often modified by vulcanization process and/or it has been reinforced by adding filler for improved properties [3]. Carbon black and silica are synthetic fillers, commonly used as reinforcing fillers in rubber industries. Currently, natural fillers become a good choice of reinforcing agent in natural rubber because they are biodegradable, environment friendly, inexpensive and reducing domestic waste [4].

In agricultural countries, rice husk is one of the major agricultural residues generated from the rice milling process. Rice husk is mostly used as a biomass fuel in the milling plants and power plant. A by-product from burnt rice husk is called rice husk ash [5]. Rice husk ash is mainly composed of silica ( $\text{SiO}_2$ ) (over 80-90%) and carbon black. Rice husk ash has been studied to be used as reinforcing filler in natural rubber composites. Previously, natural rubber composites were produced from natural

rubber mixed with rice husk ash in solid form by two-roll mill (conventional process). The limitations of this method are the low filler loading (not over 60 phr) and inferior dispersion of filler in natural rubber composite [6-9]. The latex compounding method was then developed to solve the problem of incompatibility between rubber and filler and to improve the dispersion of fillers in the natural rubber matrices. Moreover, the latex compounding method had lower energy consumption during mixing when compared to the conventional process [10].

Alginate is a polysaccharide and has widespread applications in the food and drinks, cosmetic, pharmaceutical and bioengineering industries because it has unique structure, biocompatibility and biodegrade-ability [11]. Alginate has been commonly used as thickening agent and gelling agent. It is soluble in water and becomes hydrogel at various temperatures. Each amount of its usage for applications is lower in comparison to other substances. Modification by crosslinking is expected to widen its application [12].

Silica as dielectric metal oxide semiconductor has dielectric constant about 3-9 and is used in micro and nano electronic industries [13]. Recently, the electric and dielectric properties have attracted much interest because they are important in predicting the behavior of the product as material for the application in microelectronics, batteries, sensors, fuel cells and super capacitors [14].

The aims of this study are to improve mechanical and chemical properties of natural rubber composite films reinforced with different types of rice husk ash via a latex aqueous micro-dispersion process. In order to obtain good dispersion of polar fillers in a nonpolar NR matrix, sodium alginate, one of the most commonly used natural polysaccharides, was employed as a thickening and dispersing agent in the mixture. Through the use of this technique, high concentrations of fillers can be added into the NR matrix without phase separation. The effects of reinforcing NR composites with RHAs and different crosslinking agent on the chemical, mechanical, biodegradation and dielectric properties were investigated for further development of the composite films.

## 1.2 Objectives

- To prepare and investigate chemical and mechanical properties of natural rubber composites filled with different types of rice husk ash prepared via a latex aqueous micro-dispersion process
- To compare electrical properties of the fabricated natural rubber composites treated with different cross-linking agents

## 1.3 Scopes of this research

- Rice husk ashes in this research are
  - 1) BRHA is original black rice husk ash from rice milling plant.
  - 2) BRHAT is BRHA that is treated by acid washing, using hydrochloric acid for removing impurities.
  - 3) WRHA is obtained from the controlled combustion of rice husk under the burning temperature at 500°C for a period of  $\approx$  2 hours.
- Preparation of natural rubber composites via a latex aqueous micro-dispersion process.
- Utilization of alginate for filler dispersion.
- Investigation for effects of types of fillers (BRHA, BRHT and WRHA) and the amount of filler loading at 0, 20, 60 and 100 phr.
- Investigation for effects of crosslink agents in natural rubber crosslinking processes (sulfur vulcanized and alginate crosslinked with  $\text{CaCl}_2$ ).
- Characterization of chemical and mechanical properties of natural rubber composites:
  - 1) Chemical properties
    - Morphology
    - Overall components
    - Particle size distribution
    - Structural information
    - Functional groups and possible interaction between fillers and natural rubber
    - The solvent uptake
    - Water absorption
    - Biodegradation in soil

2) Mechanical properties

- Tensile strength
- Young modulus
- Elongation at the break

3) Electrical conductivity, dielectric constant and dielectric loss of natural rubber composite were studied.

## CHAPTER II

### BACKGROUND AND LITERATURE REVIEWS

#### 2.1 Natural rubber

The major commercial source of natural rubber latex (NRL) is *Hevea brasiliensis* which originated from Amazon Forest in South America. Generally, fresh natural rubber latex (FNRL) is composed of about 30-40 wt% dry rubber content (DRC) and non-rubber components of small amounts of proteins, carbohydrate and lipids as shown in Table 2.1. Non-rubber components in NRL causes latex destabilization due to promotes the growth of bacteria. To ensure long term storage, ammonia is often added to the latex in very small amounts to maintain physical properties and prevent coagulation during transportation and storage [15, 16]. The fresh NR latex is often modified to concentrated natural rubber latex (CNRL) with about 60 wt% DRC by centrifugation as Figure 2.1. After the centrifugation process, the leftover suspension, or skim natural rubber latex (SNRL), is composed of about 4-6 wt% DRC, and typically used to produce lower grade products such as car mats and bicycle wheels. Besides the DRC contents, the latex particle sizes also affect the mechanical properties of NRL [17-19].

**Table 2. 1** Composition of fresh natural rubber latex [18]

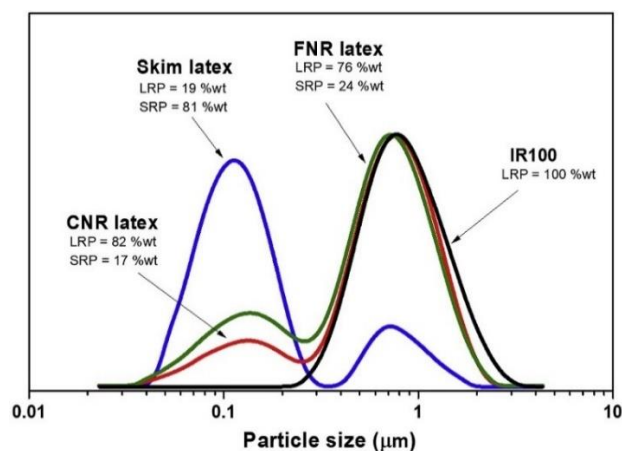

Compositions	Content (%)
Rubber hydrocarbon	30 - 40
Protein	1.5
Carbohydrate	1.5
Lipids	1.3
Organic solutes	0.5
Inorganic substances	0.5
Water	55 - 60

NR latex is colloidal suspension of rubber particles dispersed in water. Latex colloids from Hevea tree commonly shows a bimodal particle size distribution, which can be classified into small rubber particles (SRP: particle size between 10 and 250 nm) and large rubber particles (LRP: particle size between 250 nm and 3  $\mu\text{m}$ ). Specific weight of fresh NR latex is 0.96 – 0.98 g/cm<sup>3</sup> and its pH is varying within 6.5 – 7.0.

**Figure 2. 1** Production of concentrated natural rubber latex

From the centrifugal process, the supernatant SNRL contains mostly small particles (81 wt% SRP + 19 wt% of LRP), whereas FNRL is most composed of large particles (24 wt% SRP + 76 wt% LRP) [17]. The difference in particle size distribution also results in branch point structures after drying, leading to the different characteristics and properties [17, 20].

**Figure 2. 2** Particle size distributions of FNRL, CNRL, and SNRL compared with synthetic polyisoprene (IR100).

NR has many advantageous properties, such as high elasticity, flexibility at low temperatures, resistance to abrasion, to impact and corrosion, facile adhesion to textiles, insulating properties and ability to disperse heat. The properties of NR are suitable for requirements of multiple products. Therefore, NR is used extensively in many applications and products such as glove, adhesives, health equipment and accessories, coatings, condoms, and floor [21].

NR is a biopolymer of cis-1,4-polyisoprene. The chemical structure of NR is shown in figure 2.3. NR rubber is a highly non-saturated rubber because each its structural unit contains an unsaturated bond or double bond. Thus, it is easy to react with ozone, oxygen and ultraviolet light, which cause its very low aging resistance [3]. For this reason, the properties of NR need to be improved by a process, such as vulcanization and/or another reinforcement process.

**Figure 2. 3** Chemical structure of cis-1,4-polyisoprene

Vulcanization is a reaction that leads to the formation of crosslinks between polymer chains. This process can improve NR mechanical properties such as tensile strength. The vulcanizing agent is originally referred to elemental sulfur. It now also includes non-sulfur systems such as peroxides and metal oxide. A crosslink may be a group of sulfur atoms in a short chain, a single sulfur atom, a carbon-to-carbon bond, a polyvalent organic radical, an ionic cluster, or a polyvalent metal ion [22]. Network formation in vulcanization process is shown in Figure 2.4

**Figure 2. 4** Network formation in vulcanization process

Types of Crosslinking system are described below:

1) Sulfur system

The crosslinks depend on sulfur level, accelerator type, accelerator /sulfur ratio and cure time. High accelerator, sulfur ratio and longer cure time increase the mono-and di-sulfidic linkages. Mono and di-sulfidic crosslinks have better solvent and heat resistance, set resistance, reversion resistance but are generally stiffer, hence lower tensile strength, crack resistance. Polysulfidic crosslinks have a better tensile strength, softer, crack resistance but lower set resistance, heat and solvent resistance [22, 23].

2) Peroxide system

Unlike sulfur vulcanization, peroxide curing does not require carbon-carbon double bonds to form crosslinks. This system is suitable for both rubbers with or without double bonds. Carbon-carbon crosslinks formed by peroxide give the rubber a stiffer structure (high modulus) [23].

3) Metal oxide system

Polychloroprene and carboxylate acrylonitrile rubbers can be crosslinked with metal oxides such as zinc oxide and magnesium oxide. The crosslinks in chloroprene rubber by zinc oxide is covalent bonding while the nitrile rubber is ionic bonding.

The mechanism of high strength in polysulfidic crosslinks is thought to be the ability to interchange with one another and redistribute local stress. Sulfur, peroxide

and radiation curing systems could produce more intra-molecular C-C links which do not contribute to the mechanical properties [24].

## 2.2 Rice husk and rice husk ash

Asia is the world's important rice-growing region with approximately 90% of total world output. Thailand has rice plantation area around 60 million rai, which yields output of around 20 million tons of milled rice. Domestic rice consumption in Thailand is around 10 million tons of milled rice (50% of all rice). Export markets include China, the United States, ASEAN countries, and Africa. Export rice are generally of white rice, parboiled rice, and Thai jasmine rice [25].

Rice husk is the outer layer of rice grain, which is an agriculture by-product of the rice milling industry. It is reported that chemical content of rice husk consists of 50% cellulose, 25-30% lignin, and 15-20% silica [26]. The rice husk is also used as a biomass fuel in steam boiler to generate hot steam in the power plant and rice milling plant. Burning rice husk as fuel results in the production of rice husk ash as a waste material.

Rice husk ash produced from burning rice husks at a temperature of 400°C - 500°C is in form of amorphous silica. But, by burning at temperatures greater than 1,000°C, rice husks will turn into crystalline silica. The resulting amorphous silica from rice husk ash is suspected as an important source to produce pure silicon, silicon carbide, and silicon nitride flour [27]. Rice husk ash is rich in silica (SiO<sub>2</sub>) over

80-90%. Silica is used in many applications such as in pharmaceutical products, vegetable oil refining, detergents, chromatograph column packing, ceramics etc.[28]. Many research have been developed to produce high purity silica with large surface area using rice husk or rice husk ash such as:

*Sankar et al.(in 2016)* produced nanosilica powder from three kinds of rice husks. Their methods were: 1) combustion of rice husk in the open, 2) acid leaching and 3) incineration at 700°C under atmospheric conditions. The results showed that spherical and completely amorphous silica particles with large specific surface area and composed only by Si and O were obtained from all kinds of rice husks [29].

*Bakar (in 2016)* investigated the conditions to obtain high purity silica from rice husk by acid leaching and incineration at different temperatures under atmospheric conditions. The result indicated that rice husk leached with HCl produced the highest content of amorphous silica (99.6%) at 600 °C [30] .

*Yalçin and Sevinç(in 2001)* reported that the highest purity silica from rice husk was obtained with prior acid treatment and incineration in oxygen atmosphere. Silica from this study was amorphous silica particles with maximum specific surface area of 321 m<sup>2</sup>/g and 99.7% purity [31].

*Fernandes et al. (in 2017)* showed that it is possible to produce silica from rice husk ash with purity above 98%, by using simple methods. The treatments that afforded the best results were acid leaching followed by thermal treatment at 800°C, and alkaline extraction at low temperature, in which products with silica purity of 99.3% and 99.6%, respectively could be obtained [32].

Several studies might use different chemical and thermal treatment approaches, but they all reported that by acid leaching pretreatment followed by oxygen-rich incineration, the combustion of rice husk produced the highest silica content. The atmosphere with the highest partial pressure of oxygen induced the chemical reduction of carbon and was more efficient than the other atmosphere settings [33].

Rice husk ash has high silica contents, and it is available in abundant with low cost. In recent years, rice husk ash has been widely used as construction material such as pozzolana in concrete, or as adsorbent to adsorb organic dye, inorganic metal ions and insulation boards [34]. In addition, rice husk ash is widely used as natural filler in rubber industry. It can be used as an additive agent for improved tensile strength of natural rubber. Moreover, it is also used to reduce the cost of rubber compounding and reduce wastes from landfills.

### **2.3 Alginate**

Alginates are present in nature as one of the constituents of brown algae (*Phaeophyceae*) and as capsular polysaccharides in soil bacteria. The commercial alginates are currently obtained from algal sources. Alginate is the most abundant

marine biopolymer and occurs in the intercellular mucilage and algal cells of brown seaweeds in the form of calcium, sodium and magnesium salts of alginic acid [11].

The structure of sodium alginate is represented in Figure 2.5. Alginate is a binary linear heteropolysaccharides containing 1,4-linked  $\alpha$ -l-guluronic acid and  $\beta$ -d-mannuronic acid. Alginate has been widely used in the field of controlled release, ion exchange, and in the vapor-permeation membrane-separation technique [35, 36]. To make stable water-insoluble alginate products, alginic acid is transformed by incorporating different salts. This produces Na-, K-,  $\text{NH}_4$ -, Mg-, and Ca- alginate.

**Figure 2. 5** Chemical structure of sodium alginate

Alginate has widespread applications in the food and drinks, pharmaceutical and bioengineering industries [37]. In addition, the crosslinked sodium alginate was highly stable, flexible and easy to use. When sodium alginate is put into a solution of calcium ions, the calcium ions replace the sodium ions in the polymer. Each calcium ion can attach to two of the polymer strands that is called cross-linking alginate. The crosslinking is achieved by the ionic interaction between calcium ions and the carboxyl groups of the blocks of guluronic acid residues of two neighboring alginate chains, resulting in formation of stable three-dimensional network [38, 39].  $\text{Ca}^{2+}$  is preferred to crosslink alginate for biomedical applications due to the mild reaction conditions. Calcium salts suitable for crosslinking alginate include  $\text{CaCl}_2$ ,  $\text{CaSO}_4$ ,  $\text{CaCO}_3$ , calcium acetate, calcium ascorbate etc. [40]. There are a few research studies about blending alginate with natural rubber such as below:

*Riyajan and Tangboriboonrat (in 2014)* studied about blending NR with sodium alginate solution and coconut waste used as a cofiber for absorption of lead

ions ( $\text{Pb}^{2+}$ ). After being cross-linked by calcium chloride, the beads were highly stable, flexible and easily used in the environment. The cofiber increased the porosity and contact. The adsorption efficiency of the composite beads was up to 99.6% of the  $\text{Pb}^{2+}$  [41].

*Riyajan (in 2017)* investigated novel bead of modified starch for encapsulating 2,4-dichlorophenoxy acetate (2,4 DA) was made from NR-graft-cassava starch and sodium alginate in a water-based system. The results suggested that NR with sodium alginate matrix was a good polymer membrane for encapsulating 2,4 DA in a water medium and the beads were also easily decomposed in the natural environment after use [42].

However, no studies so far have investigated the use of alginate as a dispersing agent and binder for the fabrication of rice husk ash filled-NR composite films and the effect of crosslinking by  $\text{CaCl}_2$  on the NR composite films.

## **2.4 Improvement properties of natural rubber composites with fillers**

### **2.4.1 Reinforcing agents for NR**

Fillers are solid substances that are added to rubbers for many reasons, such as modification physical properties, modification processing performance, reinforcement and reducing production costs. The two types of common fillers are reinforcing and diluent (or non-reinforcing) fillers [43]. Silica and carbon black are widely used for reinforcement in NR because it can improve the mechanical and other related rubber product properties. Carbon black has been used as reinforcing material in tire industries for long times, whereas silica is only limited to colored rubber products.

#### **1) Silica**

Silica is a strongly polar and hydrophilic reinforcing filler. The conventional silica is white in color. Many researchers reported that adding silica into rubber compounds can improve mechanical properties such as hardness, tensile strength and tearing energy. Silica contains high silanol groups on its surface and these polar groups promote strong particle–particle interaction leading to high degree of aggregation and agglomeration of silica particles and low compatibility with non-polar rubbers, which result in poor dispersion. The structure of silica aggregates in

rubbers can be adjusted by modifying the filler surface to increase the compatibility of silica with hydrocarbon rubbers in order to improve the filler dispersion [44].

For unvulcanized NR with silica, the lipid and protein in natural rubber may induce hydrogen bonding between rubber and silanol group on surface of silica as shown in Figure 2.6. The proteins in natural rubber have a similar effect as silane on the silica surfaces, although not as strong [45, 46].

**Figure 2. 6** The interactions between silanol groups of silica and proteins in NR via hydrogen bonding with functional groups: (a) amino group and (b) carboxyl group.

Successful use of silica for rubber reinforcement therefore requires commonly silane coupling agents to enhance silica–rubber interaction and silica dispersion as well as to prevent accelerator adsorption on the silica surface. Silane coupling agents in rubber systems are TESPT28 and bis(triethoxysilylpropyl) disulphide (TESPD) [47].

## 2) Carbon black

Carbon black is the most traditional and commonly used reinforcing filler because of the hydrophobic surface of carbon black filler matched to hydrophobic surface of NR. The size of carbon black aggregate of 0.1-0.2  $\mu\text{m}$  is also important in determining the carbon black reinforcement in natural rubber. The agglomeration of carbon black can form aggregate of 10-1000  $\mu\text{m}$  in size. The filler–filler interaction of carbon black is due mainly to weak Van der Waals forces that degrade easily during mixing [48, 49].

*M Kardan (in 2004)* indicated that the active carbon black was more effective when the rubber was originally in cis-conformation as opposed to trans-

conformation. In addition, reinforcing carbon black did not participate in any crosslinks within the elastomer network. The carbon black reinforced the rubber structure by means of the formation of a network of entanglements or mechanical interlocking forces [50].

However, the production and use of carbon black may cause environmental problems because carbon dioxide is released into the atmosphere during the production of carbon black. Many researchers involved replacing the carbon black with other eco -friendly fillers such as fly ash and wastes from agricultural biomass.

### 3) Fly ash

Fly ash is a byproduct of the power generation industries. The main component of fly ash is silica. For many years, fly ash can be used as a potential reinforcing filler to improve the mechanical properties of rubber compound.

*Panitchakarn et al. (in 2019)* developed composite films composed of uncured NR combined with coal fly ash that obtained from pulping facility in Prachinburi province, Thailand. The results indicated that mechanical properties and structural stability of NR composite film were improved at coal fly ash content of 20 phr. The tensile strength, elongation at break and Young's modulus of composite film increased to 10.5 MPa, 222% and 126 MPa, respectively, which were 8.7, 2.2, and 52.5 folds when compared to the original NR [51].

*Arti Maan et al. (in 2014)* found that the particle size of fly ash had significant effect on mechanical properties of NR composite. The composite had higher tensile strength, density, hardness, abrasion resistance, skid resistance and water absorption at small particle size (25  $\mu\text{m}$ ) of fly ash. This is due to lower surface area of higher particle size fly ash available for interaction with rubber matrix than lower particle size fly ash at same loading [52].

*Yangthong et al. (in 2019)* studied novel epoxidized natural rubber (ENR) composites with geopolymers (GP) from fly ash waste. The result indicated that the ENR/GP composites with 15 phr GP were the highest tensile strength because of the maximal chemical linkages of hydroxyl groups and metal oxides on GP surfaces and epoxide groups in ENR. The possible reaction mechanism of the polar functional

groups on GP surfaces is shown in Figure 2.7. The silanol groups on the GP surfaces interacted with the polar functional groups in epoxide rings and with the opened ring products of ENR during vulcanization [53]. Their results showed that fly ash can be used as reinforcing filler to improve mechanical properties of NR composites.

**Figure 2. 7** The chemical reactions between ENR and GP

#### 2.4.2 NR composites with rice husk ash

Natural fillers are biodegradable, environment friendly and easy to get because they are in abundant quantity. In addition, natural fillers are cheap and can reduce domestic wastes. Rice husk ash is a renewable resource of silica that obtained from burning agricultural waste rice husk. The major component of rice husk ash is silicon dioxide ( $\text{SiO}_2$ ) and structure is similar to the conventional silica filler that used in the rubber industry [54]. Many studies of rice husk ash in NR compounds are shown below.

*Ishak and Bakar (in 1995)* studied two types of rice husk ash, namely white rice husk ash (WRHA) and black rice husk ash (BRHA) in epoxidized natural rubber (ENR). WRHA has about 96% silica content, while the BRHA has about 54% silica content and substantial carbon content about 44%. These ashes were mixed into ENR by two roll mixing mills. Two ashes were compared with two commercial fillers

(precipitated silica and carbon black). The results showed that overall vulcanized properties of WRHA were better than BRHA but it was inferior when compared with precipitated silica and carbon black. In addition, WRHA has high silica content but has vulcanized properties close to carbon black because of filler parameters such as surface area, surface reactivity, particle size, and metal oxide content. The addition of coupling agent of A-189 silane can improve the performance of WRHA and BRHA in ENR. Tensile and tear strengths of ENR vulcanizates increased with the addition of silane coupling agent because it helps to disperse and make chemical bonding of RHA fillers in the rubber matrix [6].

*Ismail et al. (in 1999)* studied white rice husk ash (WRHA) as filler in NR compounds by two roll mixing mills. Filler loading was 0, 10, 20, 30, 40 and 50 phr. The effect of multifunctional additive (MFA) was investigated. The results showed that the tensile and tear strengths increased with increasing WRHA loading until 10 phr after that there was the decrease in those properties because of agglomeration of filler particles. However, the tensile modulus and hardness increased with increasing filler loading. MFA loading at 3 phr was the optimal concentration for the maximum physical properties. At more than 3 phr, MFA produced weak boundary layer at interface between rubber and filler, so reducing physical properties [7].

*Sae-Oui et al. (in 2002)* studied two grades of rice husk ash (low- and high-carbon contents) as filler in NR and compared with other commercial fillers such as talcum, china clay, calcium carbonate, silica, and carbon black. Filler loading was 0, 15, 30, 45 and 60 phr. The results showed no significant difference in filler loading of both grades of rice husk ash and inert fillers (e.g., talcum, china clay and calcium carbonate). In addition, the mechanical properties (tensile strength, modulus, hardness, abrasion resistance, and tear strength) of two grades of rice husk ash were lower than those with silica and carbon black but were comparable to those with inert fillers. Surface area and surface activity of both rice husk were very low, which was the reasons for poor mechanical properties filled vulcanizates and their porous structure caused of failure at high loading. Silane-coupling agent slightly affected the properties of the ash-filled vulcanizates because of the lack of silanol groups on the ash surface [8].

*Siti Salina Sarkawi and Yusof Aziz (in 2003)* studied ground rice husk without burning as filler in rubber vulcanizates by two roll mixing mills. Rice husks were sieved to 300  $\mu\text{m}$  and 180  $\mu\text{m}$ . Filler loading was varied from 0 to 50 phr and was compared with carbon black and silica. The results showed that the tensile strength and elongation at break of both size rice husk increased up to 10 phr and then it tended to decrease as the concentration of rice husk increased. Rice husk had less significant effects on hardness property because the non-reinforcing nature of rice husk. However, the physical properties of rice husk-filled vulcanizates were lower than those of carbon black but were comparable to silica. The effect of particle size of fillers is shown in tensile strength, elongation at break and abrasion of NR composites. Under the study of effect of particle size of rice husk ash, it was indicated that rice husk ash with the particle size of 180  $\mu\text{m}$  was better than that of 300  $\mu\text{m}$  because the fillers with finer and smaller particle size were better dispersed in rubber compound [34].

*Arayaprane et al. (in 2005)* compared rice husk ash filled in NR with two commercial reinforcing fillers (silica and carbon black). Filler loading were varied from 0 to 40 phr. The results are showed that lower Mooney viscosity and shorter cure time could improve hardness but decreased tensile strength and tear strength. However, the NR composites reinforced with silica and carbon black were better mechanical properties than those with rice husk ash because silica and carbon black had highly surface area (small particle size) and surface activity. The dispersion of rice husk ash in the rubber matrix was investigated by scanning electron micrographs (SEM) and the result indicated that the dispersion of rice husk ash filler in the rubber matrix is discontinuous. Therefore, rice husk ash filled NR composites had a weak structure when compared to those with carbon black and silica [9].

*Pongdong et al. (in 2015)* used rice husk ash as reinforcing filler in epoxidized natural rubber (ENR) with various loading levels (0, 10, 20, and 30 phr) and compared with silica filler. The results indicated that rice husk ash caused faster curing reactions and increased Young's modulus and tensile strength of the composites relative to the unfilled composites. This might be attributed to the metal oxide impurities in rice husk ash that could enhance the crosslinking reactions, thus increasing the crosslink density. In addition, the mechanical properties and curing

behavior were improved by silanization with bis(triethoxysilylpropyl) tetrasulfide (Si69). The rubber-filler interactions reinforced the composites is suggested as shown in Figure 2.8 [54].

**Figure 2. 8** The reaction models for rice husk ash or silica dispersed in ENR matrix (a) without silanization, (b) with silane coupling agent (Si69).

All the above studies focus on studying mechanical properties of NR composite with rice husk ash that preparing from solid NR. The limitations of their research are filler loading (not over 60 phr) and inferior dispersion of filler in NR composites.

## 2.5 Dielectric properties of composites with silica or rice husk ash

Dielectric materials can be used to store electrical energy in the form of charge separation when the electron distributions around constituent atoms or molecules are polarized by an external electric field. Dielectric analysis is important in case of batteries, sensors, fuel cells, super capacitors and in the development of microelectronic packaging materials for performance optimization of high frequency devices [14].

Measurement of dielectric properties involves measurements of the complex relative permittivity ( $\epsilon$ ), which consists of a real part and an imaginary part. The real

part of the complex permittivity, also known as **the dielectric constant** ( $\epsilon'$ ) is a measure of the amount of energy from an external electrical field stored in the material. The imaginary part is zero for lossless materials and is also known as **loss factor or dielectric loss** ( $\epsilon''$ ). It is a measure of the amount of energy loss from the material due to an external electric field. **The loss tangent** ( $\tan \delta$ ) (dissipation factor or loss factor) represents the ratio of the imaginary part to the real part of the complex permittivity

$$\tan \delta = \frac{\epsilon''}{\epsilon'}$$

Dielectric loss (loss tangent or  $\tan \delta$ ) quantifies a dielectric material's inherent dissipation of electromagnetic energy (for example, as heat due to the charging and discharging of capacitor). Dielectric losses depend on frequency and the dielectric material. Heating through dielectric loss is widely employed industrially for heating thermosetting glues, for preheating plastics before molding, and for fast jelling and drying of foam rubber.

In communication systems, higher the dielectric loss means higher the attenuation and hence it is a limitation for long range transmission. At low frequencies, the overall conductivity can be made up of many different conduction mechanisms, but ionic conductivity is the most prevalent in moist materials. The ionic conductivity of materials will contribute to the dielectric loss [55, 56].

Previous studies about dielectric properties of composites with silica or rice husk ash are summarized as below:

*Louis and Sudha (in 2014)* investigated dielectric properties of LDPE composites with rice husk ash and hydrated silica at different filler concentrations. The results showed that dielectric constant depended both on amount of filler as well as the frequency. The composites showed higher dielectric constant at lower frequencies. In addition, the optimum hydrated silica filled composite (30 parts/100 parts of LDPE) exhibited good dielectric constant and increased dielectric loss, which led to the application as a good insulator. LDPE filled with rice husk ash can be used as high frequency dielectrics due to low dielectric loss because of the non-polar nature of rice husk ash [57].

*Ahmed A. Al-Ghamdi et al. (in 2016)* studied the electric, dielectric and microwave properties of NR-based composites comprising dual phase fillers prepared from furnace carbon black or conductive carbon black with a different amount of silica. The measurements were carried out at room temperature and incident power at the inlet of the coaxial measuring line varying from 800  $\mu$ W up to 1300  $\mu$ W within the frequency range of 1 GHz to 12 GHz. The results indicated that the carbon phase had a marked strong effect on properties mentioned above. The interpenetration of the two filler phases and the grade of isolation of the conductive carbon phase by the dielectric one depended on the ratio between them. With an increasing amount of the dielectric phase in the hybrid fillers, the electric conductivity and dielectric constant of the composites was lower, while their ability to absorb electromagnetic waves enhanced. The properties of composites make them suitable for several applications such as electromagnetic interference shielding materials, antennas for mobile devices, automobiles, sensors and military-related applications [58].

*Khor et al. (in 2016)* determined the dielectric properties of mixture of rice husk (RH), rice husk ash (RHA) with rice bran (RB) on different ratios in low frequency range (from 4 Hz to 1 MHz). The results indicated that the mixture of RHA and RB was a dipolar relaxation occurring between  $10^3 - 10^5$  Hz and the peak was depressed and shifted to lower frequency as the RB content increased in the mixture. Moreover, AC conductivity decreased as the RB content increased. This might attribute to the production of natural oil content from RB. The conductivity was found to increase with the increase of RHA content. Silica is a major component in RHA that may react with the element calcium from RB, forming a compound with greater insulation properties. The result also indicated that amount of mobile carries was subjected to the RHA content [14].

The electrical properties (dielectric constant, dielectric loss and electrical conductivity) of NR composites filled with different types of filler are shown in Table 2.2.

**Table 2. 2** Dielectric properties and electrical conductivity of NR composites with various fillers

Matrix	Filler	Frequency (Hz)	Dielectric constant	Dielectric loss	Electrical conductivity ( $1/\Omega\cdot\text{m}$ )	Ref.
NR	furnace carbon black	$3 \times 10^9$	3.8	0.010	$4.5 \times 10^{-4}$	[58]
NR	conductive carbon black	$3 \times 10^9$	112	20	$2.8 \times 10^{-2}$	
NR	graphite	$10^3$	4.500	3.5	$2.2 \times 10^{-2}$	[59]
NR	carbon black	$10^3$	5	3.5	1.4

NR	barium titanate/tannic acid-ferric ion/silver	$10^3$	3.7	0.018	$1.0 \times 10^{-10}$	[66]
NR	Graphene Nanoplatelets /Carbon Black	$10^4$	3.3	12	-	[67]

## CHAPTER III EXPERIMENTS

### 3.1 Summary of scope and methodology

Experiments in this work can be described using the following diagram. Detail of each section was explained in this chapter.

**Figure 3. 1** Diagram of fabrication and characterizations of NR composites with RHAs

### 3.2 Materials

Rice husk and rice husk ash were obtained from a rice milling plant in Phra Nakhon si Ayutthaya province, Thailand that show in Figure 3.2. NR latex with a 60% dry rubber content was purchased from the Rubber Research Institute of Thailand, Bangkok, Thailand. Hydrochloric acid, sodium alginate and calcium chloride were purchased from Sigma-Aldrich (Thailand) Co Ltd., Bangkok, Thailand. Zinc oxide (ZnO), Potassium laurate (K-laurate), Potassium hydroxide (K), Zinc diethyldithiocarbamate (ZDEC), Wingstay-L (WSL) and Sulfur were purchased from the Rubber Research Institute of Thailand.

**Figure 3. 2** Rice husk (a) and black rice husk ash (b) from rice milling plant

### 3.3 Methods

#### 3.3.1 Preparation of rice husk ash

1) Black rice husk ash (BRHA) used in this study was provided by Nakhon Luang Rice Mill (Phra Nakhon Si Ayutthaya, Thailand), in which the combustion process was under oxygen depleted atmosphere due to the limited air supply. BRHA from a rice milling plant was dried in an electric oven at 105°C for 12 h to remove water and stored in a glass bottle container at room temperature (~30°C).

2) BRHA was further treated by acid-washing pretreatment in order to obtain purified BRHA ash, namely BRHAT.

The dried BRHA was pretreated by 20%w/w hydrochloric acid under L/S ratio of 20 ml Acid / g BRHA. The mixture was stirred at 80°C for 2 hours to remove impurities. After that, the solid sample was filtered from the acid solution and rinsed

repeatedly with deionized (DI) water until the solution was neutral pH and then dried overnight at 105°C. The product from the pretreatment of BRHA is referred as “BRHAT”.

3) White rice husk ash (WRHA) was prepared in our laboratory (Chulalongkorn University, Bangkok, Thailand). Initially, rice husks were washed with distilled water to remove dirt and impurities and then were dried in an oven at 105°C for 24 h. The dried rice husks were submitted to the heat treatment in ceramic crucibles, which was carried out in an atmosphere of air in an electric furnace at the temperature of 500°C for 2 h [68].

The particle sizes of three types of rice husk ashes were reduced using ball milling (PM 100, Haan, Germany) at revolution speed 400 rpm for 15 min and sieved (Test sieve ASTM, 203x50 mm, 106  $\mu\text{m}$ , 140 meshes) in order to obtain the powder with a size of less than 106  $\mu\text{m}$ .

### **3.3.2 Preparation of natural rubber composite films**

The NR composite films were reinforced by using BRHA, BRHAT and WRHA as filler. The filler loading used in this work was varied at 0, 20, 60 and 100 per hundred rubbers (phr). The microdispersion process [51] was applied for the preparation of composite films.

1) Initially, the filler was added into the aqueous solution of 1% w/v alginate (10 phr that the minimum amount of alginate for good dispersion of filler loading 20-100 phr, observation from smooth surface of composites after fabrication). Then, the slurry was thoroughly mixed under mechanical stirring at room temperature for 30 min.

2) Then, 5 g of 60 phr NR latex was slowly added into 30 mL of the slurry under continuous mixing by high-frequency mechanical stirring until the mixture was homogenous.

3) After that, the mixture was poured into a plastic tray and dried overnight (~12 h) in an oven at 40°C to obtain NR composite films.

The composite films of NR combined with BRHA, BRHAT and WRHA are referred to as NR–B, NR–T and NR–W, respectively.

### 3.3.3 Crosslinking with CaCl<sub>2</sub>

The aqueous solution of CaCl<sub>2</sub> at 1% w/v was used as crosslinking agent. The solution was prepared by dispersing CaCl<sub>2</sub> in distilled water and stirring at room temperature for 30 min. The NR composite films were soaked in 1% w/v CaCl<sub>2</sub> solution for crosslinking of alginate for ~1 h, and then the films were rinsed with distilled water to remove excess chloride. After that, the composite films were dried in an oven overnight at 40°C [69]. After crosslinking with Ca<sup>2+</sup>, the crosslinked composite films of NR combined with BRHA and WRHA are referred to as NR–BC, NR–TC and NR–WC, respectively.

### 3.3.4 Sulfur vulcanization

Sulfur vulcanized NR composites prepared according to the following steps (the step #1 to the step #3) of micro-dispersion process. After step #1, the additives and crosslink agents were added to the slurry in proper amounts as shown in Table 3.1 and stirred at room temperature for 15 min. The NR composite films from the step #3 were cured in the oven at 110°C for 1 h. The filler loading used in this crosslinking process was at 100 phr that was RHA loading of the highest mechanical properties of uncrosslinking NR composites with RHA. The sulfur vulcanized composite films of NR combined with BRHA, BRHAT and WRHA are referred to as NR–BS, NR–TS and NR–WS, respectively.

**Table 3. 1** Formula of composite materials of sulfur vulcanization

Ingredients	Function	Sulphur vulcanization (phr)
NR latex	Matrix	100
BRHA, BRHAT, WRHA	filler	100
Alginate	Dispersant	10
KOH	Stabilizer	0.2
K-laurate	Stabilizer	0.1
Zinc oxide	Activator	0.5
ZDEC(zinc diethyldithiocarbamate)	Accelerator	1.0
WSL (Wingstay-L)	Antioxidant	1.0
Sulphur	Crosslinker	1.5

### 3.4 Characterization

#### 3.4.1 Morphology

Morphologies of rice husk ashes and composite films were observed by scanning electron microscope and energy dispersive X-ray spectrometer (SEM–EDS) (IT-500HR) using a JEOL, JSM-IT-500HR and JEOL, JED-2300 (JEOL, Tokyo, Japan). The specimens were frozen in liquid nitrogen and vacuum dried. After that, the specimens were sputtered with gold. The SEM–EDS performed at an accelerating voltage of 10 kV. 3.5.2 Fourier Transform Infrared (FTIR) Spectroscopy

#### 3.4.2 Particle size distribution

The overall components and particle size distribution of each dried sample were determined by X-ray fluorescence spectrometer analysis (Bruker model S8 Tiger, Karlsruhe, Germany) and laser particle size distribution analyzer (Mastersizer 3000, Malvern Panalytical, Malvern, UK), respectively.

#### 3.4.3 Surface, pore size and pore volume analysis

The surface area, pore volume and average pore diameter of samples were determined by nitrogen (N<sub>2</sub>) physisorption-desorption using a surface area and pore size analyzer (Autosorb-iQ-MP, Quantachrome, Boynton Beach, FL, USA).

#### 3.4.4 Structural information crystallinity

The structural information and crystallinity of fillers and NR composite films were characterized using X-ray diffractometer (XRD, Bruker AXS Model D8 Discover, Karlsruhe, Germany) with Cu-K radiation in the  $2\theta$  range of 5–40. The operation conditions were at the accelerating voltage of 40 kV and electric current of 30 mA.

#### 3.4.5 Functional groups and possible interaction

The functional groups and possible interaction between fillers were determined by Fourier transform infrared (FTIR) spectroscopy (PerkinElmer, Waltham, MA, USA) in the ranges of 4000–650 cm<sup>-1</sup> with a resolution of 4 cm<sup>-1</sup>.

### 3.4.6 Mechanical properties

For mechanical properties tests of dry film of NR, NR composites (Young's modulus, tensile strength and elongation at break) were performed using Universal Testing Machine (Instron, Norwood, MA, USA). The test conditions were according to ASTM D882. At least five specimens for each different blend composition were tested.

### 3.4.7 Water absorption capacity

The measurement of water absorption capacity (WAC) was performed by using the specimen films of 2 x 2 cm<sup>2</sup>, with a thickness of 0.5–0.6 mm. The specimens were immersed in distilled water at room temperature for 0–18 days. The specimens were removed from water every 2 days, and excess water at the surface of the samples was blotted by Kimwipes® paper. The weight of wet sample was measured. All testing was carried out in triplicate. Water absorption capacity was calculated by using the formula:

$$WAC (\%) = \frac{W_h - W_d}{W_d} \times 100$$

Where,  $W_h$  and  $W_d$  are the weights of the specimen hydrated and dried, respectively.

### 3.4.8 Toluene uptake

For the test of toluene uptake, dried sample films (2 x 2 cm<sup>2</sup>), with a thickness of 0.5–0.6 mm, were immersed in toluene at room temperature. The weight change was monitored at 1 h intervals for 8 h. All testing was carried out in triplicate. Toluene uptake was calculated by using the formula:

$$TU (\%) = \frac{W_t - W_d}{W_d} \times 100$$

Where,  $W_d$  and  $W_t$  are the weights of the specimen before swelling and after a time (t) of immersion, respectively.

### 3.4.9 Preliminary test of biodegradation in soil

For the preliminary test of biodegradation in soil, each test specimen, having 5x5 cm<sup>2</sup> and a thickness of 0.5–0.6 mm, was used for the measurement of biodegradation in soil. Potting soil purchased from a garden center (Bangkok, Thailand) was used for the experiment. The main composition of potting soil was loam soil, compost manure and coconut coir. The soil temperature was around 28–30°C. The moisture content of the soil was around 50–60%. The specimens were weighed and buried in soil at a depth of 10 cm for 3 months under ambient conditions, where the temperature range was 24 to 35°C as Figure 3.3. After 1, 2 and 3 months, the samples were removed from soil, washed with deionized water (DI) water, dried at 40°C for 12 h and recorded for their weights. The degradation was evaluated by measuring the weight loss by using the formula:

$$\text{Biodegradation (\%)} = \frac{W_0 - W_i}{W_i} \times 100$$

Where,  $W_0$  and  $W_i$  are the weights of the specimens before and after being buried in soil, respectively.

**Figure 3. 3** Biodegradation in soil testing

### 3.4.10 Electrical properties analysis of natural rubber composite films

#### 1) Dielectric properties [64]

The capacitance, resistance and dissipation factors were measured directly by using impedance analyzer with a precision impedance analyzer (4294A, Agilent, Santa Clara, California, USA) as Figure 3.4 at room temperature. The measurements were done at varying frequencies ranging from  $10^3$ – $10^6$  Hz as per ASTM standard D-150-74. The samples were coated by silver paint as electrode on both sides before measurement.

#### *Dielectric constant ( $\epsilon'$ )*

The dielectric constant of a material is defined as the ratio of the capacitance of a condenser containing the material to that of the same condenser under vacuum. The capacitance of a condenser measures the extent to which it can store charges. Dielectric constant can determine by using the following equation:

$$\epsilon' = \frac{Cd}{E_0A}$$

Where  $\epsilon'$  is dielectric constant, C is capacitance, A is surface area of sample, d is thickness of sample, and  $E_0$  is dielectric permittivity ( $8.85 \times 10^{-12}$  Farad.m<sup>-1</sup>).

#### *Dielectric loss ( $\epsilon''$ )*

The electrical loss or the amount of energy dissipated by the insulating material when the voltage is applied to the circuit can be represented by means of a dissipation factor. Most of the elastomers have lower dissipation factor at room temperature. The loss factor (dielectric loss,  $\epsilon''$ ), the dielectric constant ( $\epsilon'$ ) and the dissipation factor ( $\tan \delta$ ) are related by the following equation:

$$\tan \delta = \frac{\epsilon''}{\epsilon'}$$

## 2) Electrical conductivity [70]

The electrical properties were measured and obtained using an impedance analyzer with an LCR meter. The measured electrical resistivity of the composite materials was converted into electrical conductivity by using the following equation:

$$\rho = \frac{RA}{L} = \frac{1}{\sigma}$$

Where  $\rho$  is the volume resistivity ( $\Omega\text{m}$ ),  $R$  is the resistance ( $\Omega$ ),  $A$  is the cross-section discs ( $\text{m}^2$ ),  $L$  is the thickness (m), and  $\sigma$  is the electrical conductivity ( $\Omega\text{m}$ )<sup>-1</sup>.

**Figure 3. 4** Precision impedance analyzer

## CHAPTER IV

### RESULTS AND DISCUSSION

#### 4.1 Characterization of BRHA, BRHAT and WRHA Particles

Rice husk ash is a major by-product of the combustion of rice husk to generate heat for boilers in rice milling plants, in which the burning temperature is usually above 800 °C. BRHA results from the pyrolysis of rice husk in poor oxygen atmosphere, whereas BRHAT treated by acid washing for elimination metal oxide impurities. WRHA is a byproduct from the combustion of rice husk in atmospheric air. The color of BRHA, BRHAT and WRHA are shown in Figure 4.1. The results of XRF analysis for chemical compositions of BRHA, BRHAT and WRHA are shown in Table 4.1. The main components of BRHA BRHAT and WRHA were found to be silica as silicon dioxide ( $\text{SiO}_2$ ), at 87.0%, 90.90% and 95.3%, respectively. The minor components were alumina oxide ( $\text{Al}_2\text{O}_3$ ) and potassium oxide ( $\text{K}_2\text{O}$ ) and small amounts of  $\text{CaO}$ ,  $\text{P}_2\text{O}_5$ ,  $\text{MgO}$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{SO}_3$ ,  $\text{MnO}$ ,  $\text{ZnO}$  and  $\text{Rb}_2\text{O}$ . Moreover, the XRF data also demonstrate that small amount of the impurities in the BRHA were removed by acid washing. The BRHAT consisted only of  $\text{SiO}_2$  as the primary component (90%) along with  $\text{Al}_2\text{O}_3$  at lower levels and small amounts of  $\text{K}_2\text{O}$ ,  $\text{CaO}$ ,  $\text{P}_2\text{O}_5$ ,  $\text{MgO}$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{SO}_3$  and  $\text{MnO}$ . These results agree with those of Chen et al.[71], who reported that metal impurities were eliminated from RHA under acidic conditions. In addition, the unburned carbon or loss of ignition value of BRHA, BRHAT and WRHA were found to be about 7.8%, 7.6% and 0.1%, respectively. The color of the rice husk depends on amount of unburned carbon in the ash [72]; the reported unburned carbon contents of gray-RHA and WRHA were 2.4% and 1.4%, respectively. The product of WRHA from combustion treatment contains higher silica content than BRHA and BRHAT, but the unburned carbon content of WRHA was lower than that of BRHA and BRHAT.

**Figure 4. 1** BRHA, BRHAT and WRHA powder after grinding.

**Table 4. 1** Chemical compositions of BRHA, BRHAT and WRHA

Chemical Compositions	BRHA (%wt)	BRHAT (%wt)	WRHA (%wt)
SiO <sub>2</sub>	87.00	90.90	95.30
Al <sub>2</sub> O <sub>3</sub>	2.51	0.36	1.76
K <sub>2</sub> O	1.07	0.54	0.89
CaO	0.52	0.15	0.71
P <sub>2</sub> O <sub>5</sub>	0.63	0.13	0.57
MgO	0.32	0.19	0.36
Fe <sub>2</sub> O <sub>3</sub>	0.16	0.10	0.13
SO <sub>3</sub>	-	589 PPM	0.17
MnO	719 PPM	415 PPM	743 PPM
ZnO	64.1 PPM	-	113 PPM
Rb <sub>2</sub> O	44.4 PPM	-	-
Loss on ignition	7.78	7.63	0.11

The SEM images of BRHA BRHAT and WRHA particles are shown in Figure 4.1a, b and c, respectively. BRHA and BRHAT formed black platelets of partially crystalline oxides of silicon and others, whereas WRHA was in roughly spherical form of aggregated white powders. Three types of RHA particles were produced in a wide range of sizes, from 1 to 10  $\mu\text{m}$ . However, the average size of BRHA and BRHAT was relatively smaller, compared to WRHA.

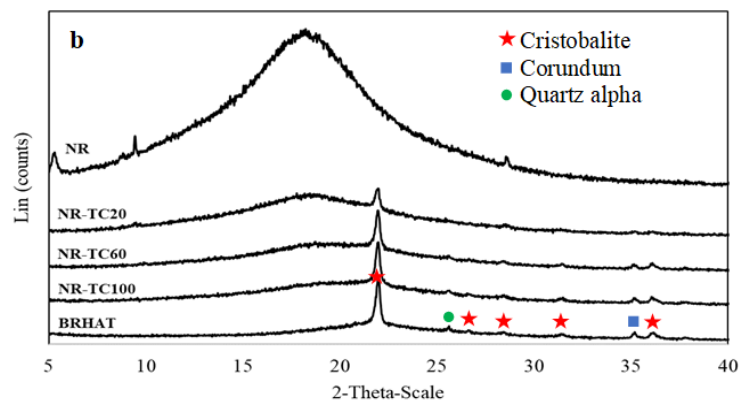

**Figure 4. 2** Scanning electron microscope (SEM) images of BRHA (a), BRHAT (b) and WRHA (c) particles.

The XRD analysis was conducted on BRHA, BRHAT and WRHA particles, as shown in Figure 4.3a-c. According to the XRD pattern, BRHA and BRHAT were in the form of partially crystalline oxides of cristobalite, corundum and quartz alpha. The observation of cristobalite and quartz alpha in BRHA and BRHAT indicates that BRHA should be treated at temperatures greater than 900 °C during the combustion process [73]. On the other hand, the XRD pattern of WRHA exhibited a very small peak of quartz alpha and broadening of the cristobalite peak (at  $2\theta = 22.5^\circ$ ), which indicates the nature of amorphous silica [74]. The degrees of crystallinity of BRHA, BRHAT and WRHA were 16.9%, 18.72% and 2.6%, respectively.

The SEM micrographs and XRD results confirm that BRHA and BRHAT are a partially crystalline silica oxide, whereas WRHA is an amorphous silica oxide. These results agree with those reported by Xu et al. and Osman et al. [75, 76], where WRHA with silica in a mainly amorphous form was produced at a controlled temperature below 800 °C, and BRHA with silica in partial crystalline phases was generated at temperatures above 800 °C.

**Figure 4. 3** X-ray diffraction of the composite films of crosslinked composite films of natural rubber (NR) combined with BRHA (NR–BC) (a), with BRHAT (NR-TC) (b) and with WRHA (NR–WC) (c) and degree of crystallinity (d) with loaded content of BRHA, BRHAT and WRHA at 0, 20, 60 and 100 per hundred rubbers (phr).

The particle size distributions of the BRHA, BRHAT and WRHA are shown in Figure 4.4. The BRHA particles ranged in size from 0.4 to ~100  $\mu\text{m}$ , with an average size  $\approx 6 \mu\text{m}$ . The d10, d50 and d90 values based on the volume distribution were 1.5, 6.2 and 28.5  $\mu\text{m}$ , respectively. The BRHAT particles ranged in size from 0.4 to ~111  $\mu\text{m}$ , with an average size  $\approx 6 \mu\text{m}$ . The d10, d50 and d90 values based on the volume distribution were 1.5, 6.1 and 25.9  $\mu\text{m}$ , respectively. The WRHA particles

ranged in size from 0.4 to 144  $\mu\text{m}$ , with an average size  $\approx 40 \mu\text{m}$ . The  $d_{10}$ ,  $d_{50}$  and  $d_{90}$  of WRHA were higher than those of BRHA and BRHAT (1.9, 17.8 and 70.4  $\mu\text{m}$ , respectively). The results from the SEM observation (Figure 4.2) and the particle size distribution (Figure 4.4) indicated that an average particle size of WRHA was larger than that of BRHA and BRHAT. This result can be attributed to hydroxyl groups of silanol (Si-OH) on the surface of rice husk ash particles. The hydroxyl group had very strong intermolecular hydrogen bonds with another hydroxyl of adjacent silica particle. These hydrogen bonds could easily cause the formation of agglomeration of particles. WRHA particles have larger particle sizes, as compared to BRHA particles, due to the higher degree of agglomeration of the WRHA powders, because of their higher silica content.

**Figure 4. 4** Particle size distributions of BRHA, BRHAT and WRHA particles.

Pore size distributions of BRHA, BRHAT and WRHA are shown in Figure 4.5. Because WRHA formed agglomerated particles, WRHA presents bimodal pore structure of two groups of pores that are considerably different in size. The small pores inside of fine particle are less than 2.5 nm, and the pores between particles are 4–30 nm. On the other hand, BRHA and BRHAT shows a monodispersed mesoporous structure. Table 2 shows surface area, pore volume and pore size of BRHA, BRHAT and WRHA particles. Owing to the smaller particle size of BRHA, the specific surface area of BRHA (51.57  $\text{m}^2/\text{g}$ ) was greater than that of BRAHT

(44.36 m<sup>2</sup>/g) and WRHA (40.06 m<sup>2</sup>/g), as the decrease of particle size resulted in an increase in surface area. The average pore volume and average pore diameter of BRHAT were lower than those of BRHA and WRHA. The pore volumes of BRHA, BRHAT and WRHA were 0.24, 0.05 and 0.48 cm<sup>3</sup>/g, respectively, with average pore diameter of 9.22, 4.89 and 23.92 nm, respectively. These results can be attributed to larger pore size in WRHA agglomerated particles.

**Figure 4. 5** Pore size distributions of BRHA (○), BRAHT (□) and WRHA (△).

**Table 4. 2** The surface area, pore volume and average pore diameter of BRHA, BRHAT and WRHA.

Rice Husk Ash	BET Surface Area (m <sup>2</sup> /g)	Pore Volume (cm <sup>3</sup> /g)	Average Pore Diameter (nm)
BRHA	51.57	0.24	9.22
BRHAT	44.36	0.05	4.89
WRHA	40.06	0.48	23.92

#### 4.2 Morphology of NR and NR Composite Films

The morphologies of the NR, NR-BC, NR-TC and NR-WC specimens are illustrated in Figure 4.6. From the outlook (Figure 4.6a), NR-BC, NR-TC and NR-WC composite films had a rather smooth surface. NR-BC and NR-TC films were black in color, whereas NR-WC films were light brown. The surface and cross-section areas of the neat NR film were smooth, whereas NR-BC and NR-WC had relatively rough surfaces. The degree of surface roughness increased with increases in BRHA, BRHAT and WRHA loading content. In addition, the cross-section area images show that BRHA, BRHAT and WRHA demonstrated homogenous dispersion in NR matrix without phase separation. SEM micrographs of surface and cross-section area of NR-W100 film without alginate are illustrated in Figure 4.7. Surface cracking presented on surface area of NR-W100 without alginate, whereas cross-section area presented the phase separation between NR and WRHA. The results reveal that alginate is a good dispersing agent for the dispersion of rice husk ashes in NR matrix up to 100 phr.

a)

b)

c)

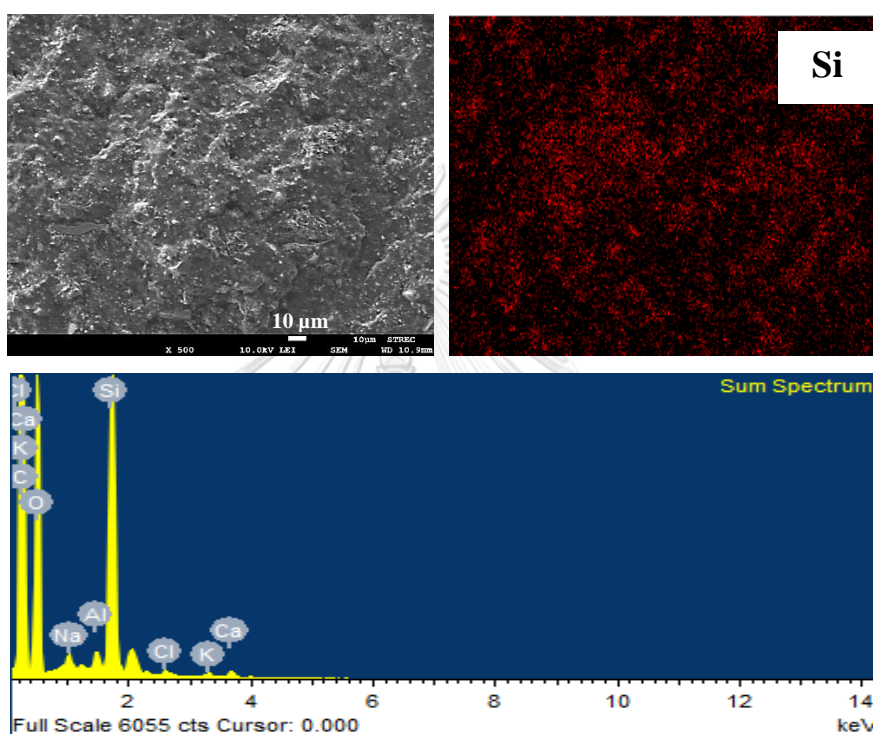

**Figure 4. 6** The outlook (a) and SEM micrographs of surface morphologies and cross-section of pure NR (b), SEM micrographs of surface morphologies of NR-BC, NR-TC and NR-WC composite films (c) and micrographs of cross-section of NR-BC, NR-TC and NR-WC films (d) at different RHA loading.

**Figure 4. 7** SEM micrographs of surface morphologies (a) and cross-section (b) of NR-W100 without alginate

The distribution of RHA in NR composites was also investigated using energy-dispersive X-ray (EDX) spectroscopy, as shown in Figure 4.8. Silicon (Si) atom, the main component in three types of RHAs was used to indicate the distribution of RHAs in the composite films. From Si-mapping, the well-distributed RHA particles were found in the EDX mapping of NR-WC composites.

**Figure 4. 8** SEM-EDX micrograph of NR-WC100 composite film

### 4.3 X-ray Diffraction (XRD) of NR and NR Composite Films

As shown in Figure 4.3, the XRD pattern of pure NR film demonstrates a broad peak with very low degree of crystallinity (0.8%), which indicates an amorphous structure for the polymer phase. NR-BC, NR-TC and NR-WC composite films revealed diffraction peaks corresponding to BRHA, BRHAT and WRHA structures, respectively. In addition, the diffraction peaks of three types of ash composites increased linearly with increasing filler loading content. The degree of crystallinity of composite films also linearly increased along with the filler loading content (Figure 4.3d).

#### 4.4 Fourier Transform Infrared (FTIR) Spectroscopy

Figure 4.9 demonstrates the FTIR spectrum of NR, BRHA, BRHAT, WRHA, NR-B, NR-BC, NR-BS, NR-T, NT-TC, NR-TS, NR-W, NR-WC and NR-WS composites. Pure NR consists mainly of cis-polyisoprene. The functional groups for identifying cis-polyisoprene were the asymmetric stretching vibration of methyl groups ( $-\text{CH}_3$ ) at  $2960\text{ cm}^{-1}$  and C-H deformation at  $1446\text{ cm}^{-1}$  [26]. The peaks observed at  $2917$  and  $1663\text{ cm}^{-1}$  are assigned to symmetric stretching vibration of methylene ( $-\text{CH}_2$ ) and C=C stretching [77]. The BRHA, BRHAT and WRHA have similar FTIR spectrum. The strong sharp peaks at  $1080$  and  $1083\text{ cm}^{-1}$  are attributed to Si-O-Si asymmetric stretching, along with peaks at  $796$  and  $800\text{ cm}^{-1}$ , which are due to symmetric Si-O-Si stretching and Si-O quartz [28, 78]. The main broad peak between  $1000$  and  $1200\text{ cm}^{-1}$  of WRHA indicates characteristics of amorphous silica [72]. The FTIR spectrum clearly indicates that functional groups found on NR-B, NR-T, NR-W, NR-BC, NR-TC, NR-WC, NR-BS, NR-TS and NR-WS are the same as those found on NR, BRHA and WRHA. The spectra of the composites contain peaks at  $2961$ ,  $2915$ ,  $1661$  and  $1067\text{ cm}^{-1}$ , which are assigned to ( $-\text{CH}_3$ ), ( $-\text{CH}_2$ ), C=C stretching and Si-O-Si asymmetric stretching, respectively. The composite films reveal a broad absorption band between  $3400$  and  $3100\text{ cm}^{-1}$ , referring to the stretching of the O-H group. The hydroxyl regions of NR-BC, NR-TC and NR-WC are more dominant than those of the composite films without  $\text{CaCl}_2$  crosslinking, which might indicate that the  $\text{CaCl}_2$  crosslinking had an effect on the O-H interaction of sodium alginate (absorption band between  $3500$  and  $3100\text{ cm}^{-1}$ ) [79]. Daemi and Barikani had previously reported that the absorption regions of O-H group in calcium alginate were narrower than the normal peak of sodium alginate, because the calcium ion decreased in hydrogen bonding between hydroxyl functional groups, resulting in narrower bands of calcium alginate [80]. The position peaks of functional groups of NR-B, NR-T, NR-W, NR-BC, NR-TC and NR-WC composite films are slightly shifted, as compared to the original spectra of NR, BRHA, BRHAT and WRHA, which indicates the formation of interactions of BRHA, BRHAT and WRHA in the NR matrix without a chemical reaction [51, 69, 77]. In case of NR-BS, NR-TS and NR-WS that were crosslinked by sulfur vulcanization but not found position peak of

functional group of C- S linkages because these peak will present in fully vulcanized compound containing more than 12% sulfur [81].

b)

c)

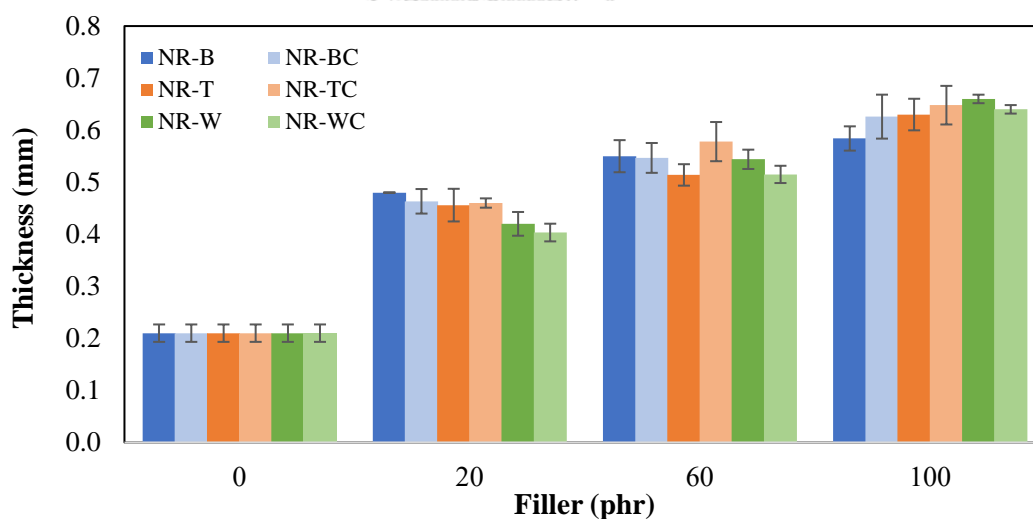

**Figure 4. 9** Fourier transform infrared (FTIR) of the BRHA; NR; NR-B100; NR-BC100 and NR-BS100 composites (a), BRHAT; NR; NR-T100; NR-TC100 and NR-TS100 composites (b), WRHA; NR; NR-W100; NR-WC100 and NR-WS100 composites (c).

#### 4.5 Mechanical Properties

The thickness NR composites with BRHA and WRHA at different filler loading are presented in Figure 4.10. The thickness of BRAH, BRHAT and WRHA composites increased with increasing filler content. Moreover, the thickness of composites after crosslinking slightly decreased in case of WRHA which may be due to some interaction between WRHA and NR matrix. The mechanical properties of BRHA, BRHAT and WRHA composites were examined in terms of tensile strength, Young's modulus and elongation at break, as shown in Figure 4.11. Uncured NR film was high elastic elongation, but it demonstrated low tensile strength. The tensile strength, Young's modulus and elongation at break of the uncured NR film were 1 MPa, 2 MPa and 113.3%, respectively. Figure 4.11a clearly shows that the addition of BRHA, BRHAT and WRHA to the NR matrix resulted in improvement among all

observed mechanical properties of the composite films. The tensile strength was relatively enhanced through the increase of BRHA and WRHA loading content in all cases. The maximum tensile strength values of the NR–B, NR–W, NR–BC and NR–WC were obtained by the filler loading at 100 phr, at 6.5, 10.4, 3.2 and 13.1 MPa, respectively. In NR–T and NR–TC composites, tensile strength increased with increasing filler content until a maximum level was reached (60 phr). The maximum tensile strength of NR–T and NR–TC were 6.7 and 5.5 MPa, respectively at 60 phr of BRHAT loading. The reduction of tensile strength may be attributed to agglomeration of BRHAT particles to form a domain that performed as a foreign particle, or result of physical contact between aggregates [82]. The results indicate that WRHA-filled NR films exhibit significantly higher tensile strength than those reinforced by BRHA and BRHAT, especially at filler loading content of 60 and 100 phr. The treatment of  $\text{CaCl}_2$  crosslinking tended to improve tensile strength of the composite films reinforced with WRHA but reduced the strength of the films reinforced with BRHA and BRHAT.

**Figure 4. 10** The thickness of the pure NR film and the NR composite films

**Figure 4. 11** Mechanical properties, tensile strength (a), Young's modulus (b) and elongation at break (c) of NR, NR-B, NR-BC, NR-T, NR-TC, NR-W and NR-WC composite with filler loading content at 0, 20, 60 and 100 phr.

The reinforcement effects on Young's modulus of composites filled with BRHA, BRHAT and WRHA were quite similar to those on tensile strength. The values of Young's modulus were improved significantly, as compared to that of pure NR film, and the values increased with increasing filler content, as shown in Figure 4.11b. The large modulus of NR composites with RHA could attribute to rubber molecule in rubber can return to their original position after being stretched. The maximum values of young's modulus of NR-B, NR-W, NR-BC and NR-WC films were obtained by BRHA and WRHA loadings at 100 phr, which were 61.1, 115.6, 58.4 and 108.6 MPa, respectively. Moreover, the maximum Young's modulus of NR-T and NR-TC films were 14.1 and 13.9 MPa that were obtained by BRHAT loadings at 60 phr. Young's modulus of BRHAT composites were lower than BRHA composites could be attributed to metal impurities in BRAH and BRHAT particles. After acid treatment, silica content in BRHA increased but  $\text{Al}_2\text{O}_3$ ,  $\text{K}_2\text{O}$ ,  $\text{CaO}$ ,  $\text{P}_2\text{O}_5$ ,  $\text{MgO}$  and  $\text{Fe}_2\text{O}_3$  contents decreased. These metal impurities might be important role to improve filler-filler and filler-rubber interactions, resulting in more improved mechanical properties of NR composites. These results agree with those of Panitchakarn et al.[51], who reported that the tensile strength and modulus of NR composite with coal fly ash that was treated by acid washing were lower than NR-composite with untreated coal fly ash.

As compared to the result of the NR film shown in Figure 4.11c, it is demonstrated that reinforcement with BRHA, BRHAT and WRHA can also improve elongation at break of the composite films. The maximum values of elongation at break of NR-B at 392.0% NR-T at 364% and NR-W at 302.7% were obtained at filler loading of 20 phr and 60 phr, which were 3.5-fold, 3.2-fold and 2.7-fold increases of that of the NR film, respectively. However, the values relatively decreased with further increases in filler loading beyond the optimal point, because the elasticity of the rubber chains was reduced when filler particles exceeded a certain amount in the rubber matrix [83, 84].

In the case of a small amount of filler in NR composite (20 phr), the tensile strength, Young's modulus and elongations at break of composites filled with BRHA and BRHAT were better than those filled with WRHA. These results might be attributable to the smaller particle size of BRHA and BRHAT, since the smaller

particle with higher specific surface area should facilitate a better filler–NR interaction [85]. However, when increasing filler loading in the NR composites to 60 and 100 phr, the tensile strength and Young's modulus of NR–WRHA were greater than those of NR–BRHA and NR–BRAHT. Thus, factors, such as surface activity, chemical composition of fillers, concentration, shape and interactions between fillers and NR matrix play important roles in the reinforcement of NR composites. As compared to BRHA and BRAHT, WRHA contains a higher concentration of silica but lower concentration of carbon. Higher concentration of silica and metal oxides in fillers could promote reinforcement in NR composites. Additionally, in this study, the solid dispersion of SiO<sub>2</sub> in NR matrix was successfully improved by the addition of alginate as dispersion agent, resulting in no phase separation at high filler loading in NR matrix. The results agree with those of previous works on vulcanized rubber composites [84, 86]; it was reported that the mechanical properties of rubber vulcanizates filled with WRHA were better than composites filled with BRHA.

Further crosslinking of the composites by CaCl<sub>2</sub> significantly improved the tensile strength of NR–WRHA, especially at high WRHA loading content. After the immersion of NR composites in CaCl<sub>2</sub> solution, calcium ion created gelation and ionic crosslinking with specific and strong interactions between Ca<sup>2+</sup> with G blocks of alginate, forming the net structure [87]. This ionic crosslinking can improve the structural stability of the composite films and reinforce filler–filler and filler–rubber interactions, resulting in enhancement of the tensile strength of the composite film. After crosslinking sodium alginate/natural rubber/coconut composite by CaCl<sub>2</sub>, the composites were highly stable [41]. However, it was found that the mechanical properties of NR–BC and NR–TC films were reduced by crosslinking the composites by CaCl<sub>2</sub>. The different effects of CaCl<sub>2</sub> crosslinking on NR–BRHA, NR–BRHAT and NR–WRHA might be attributable to differences in the porous structure of those fillers. WRHA presents bimodal porous structure with higher porosity and higher pore sizes, resulting in better dispersion of CaCl<sub>2</sub> into the mixtures and more interactions of fillers–alginate–NR of NR–W films. Consequently, alginate crosslinking with Ca<sup>2+</sup> could enhance the tensile strength of NR–WC. A similar observation was also noted by Costa et al. [86]. The efficiency and rate constant of vulcanization of NR–BRHA was found to be lower than that of NR–WRHA vulcanization, because the pores of

BRHA were too small for polymer chains to enter. Moreover, large internal surface areas might be a disadvantage, because a certain proportion of accelerator might become immobilized and inactivated. The adsorbed  $\text{Ca}^{2+}$  on surface might result in weakened filler–rubber interactions. Thus, mechanical properties of the NR–BC and NR–TC composite films were reduced by  $\text{CaCl}_2$  crosslinking.

Table 4.3 shows the results of mechanical properties of BRHA, BRHAT and WRHA composites crosslinked with sulfur vulcanization with RHA loading at 100 phr in comparison to those of the films of neat NR and NR reinforced with RHA loading at 100 phr with/without  $\text{CaCl}_2$  crosslinking. The results revealed that the mechanical properties of vulcanized NR composites were larger than neat NR film. Sulfur vulcanization generally changes the physical properties of natural rubbers. The hardness, modulus and tensile strength of vulcanized rubber increased, whereas elongation at break and solubility in solvents decreased when comparing to neat NR. All those changes could attribute to the degree of cross-linking in the rubber network [88]. In addition, tensile strength and elongation at break of sulfur vulcanized composites were relatively higher than tensile strength and elongation of NR-RHA composites with/without  $\text{CaCl}_2$  crosslinking. However, Young's modulus of sulfur vulcanized composites was lower than that of the NR composite films with/without  $\text{CaCl}_2$  crosslinking. In part of chemical mechanism of crosslinking by vulcanization process, the flexible NR molecular chains joined together by covalent bonding giving rise a three-dimensional network that resulted in enhance of tensile strength of vulcanized NR composites [89]. These results agree with those reported by Wahab et al. [90], who identified increment in tensile strength of thermoplastic elastomers from high-density polyethylene/NR/thermoplastic tapioca starch, indicating the increase in blend stiffness. In addition, the vulcanized NR process can prevent or reduce ability of polymer chains in NR to slip over each other result in a more rigid polymer blend. Interestingly, at the same RHA loading, tensile strength of NR-WC100 was only slightly less than that of NR-WS100. This result indicated ionic crosslinking alginate with  $\text{CaCl}_2$  could effectively improve mechanical properties without using toxic chemical in crosslinking process.

**Table 4. 3** Mechanical properties of NR, NR composites cross-linked with CaCl<sub>2</sub> and NR composites cross-linked with sulfur vulcanization.

NR composites	Young's modulus (MPa)	Tensile strength (MPa)	Elongation at break (%)
NR	2.07 ± 0.55	1.02 ± 0.05	113.30 ± 12.56
NR-B100	61.07 ± 3.66	6.58 ± 0.32	180.00 ± 23.25
NR-T100	12.41 ± 2.03	4.90 ± 0.49	175.50 ± 23.51
NR-W100	15.57 ± 4.25	10.44 ± 0.56	149.00 ± 16.31
NR-BC100	58.43 ± 4.45	3.24 ± 0.22	173.53 ± 10.28
NR-TC100	12.57 ± 0.39	4.46 ± 0.26	156.01 ± 18.29

NR-BS100	6.11 ± 0.96	11.67 ± 0.89	336.00 ± 15.75
NR-TS100	5.80 ± 0.64	11.37 ± 0.51	320.67 ± 17.91
NR-WS100	12.89 ± 0.95	13.19 ± 0.25	321.30 ± 29.45

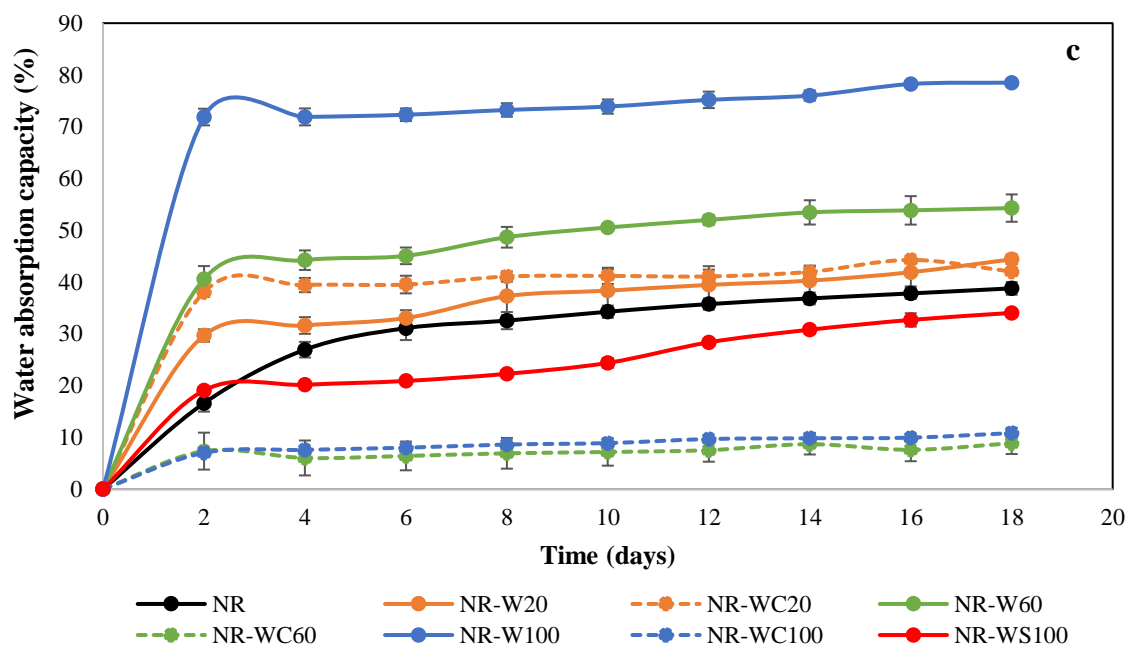

The previous studies demonstrated the limitations of polar filler loading in NR composites. They found the tensile strength of the NR composite increased with increasing the filler content up to a maximum value (20–60 phr) and then decreased [6, 8, 83, 84, 91]. Higher filler loading in NR composite could lead to formation of filler agglomeration and undispersed filler in NR matrix, resulting in a weak filler–rubber interaction. RHA has high surface polarity and strong filler-filler interaction, which leads to filler agglomerates and poor RHA dispersion in NR matrix, resulting in low mechanical properties of NR composite. The present study demonstrates that the tensile strength of uncured NR composites increases with increasing BRHA and WRHA loading, and that the maximum tensile strength was obtained at BRHA/WRHA loading of 100 phr. The results indicate that the latex aqueous microdispersion process with dispersing agent is suitable for composite preparation to achieve homogeneous dispersion of RHA fillers in NR matrix. Sodium alginate is suitable for the use as a dispersing agent in this system, because it can improve RHA dispersion and reduce filler-filler interactions. Previously, sodium alginate as a dispersing agent was proven to improve the stability, filler dispersion and viscosity of

composites of NR–coal fly ash [51], NR–sago starch [92] and NR–microfibrillated cellulose [93].

#### 4.6 Water Absorption Capacity

In the water sorption and toluene sorption tests, the length and width of the film specimen were 2 cm and 2 cm. The thickness was 0.5–0.6 mm. The film thickness slightly increased with increasing filler content but was not significantly changed by  $\text{CaCl}_2$  cross-linking. The results of the water absorption capacity (WAC) tests of NR and NR composites filled with BRHA, BRHAT and WRHA are presented in Figure 4.12. The WAC of NR film was lower than NR–B, NR–T and NR–W films, due to the hydrophobic nature of NR. The water absorption of NR film was nonlinearly increased during a period of 0–6 days for water uptake of 0–31% and then was slightly increased during the immersion in water for 6–18 days. The water absorption behavior of filled polymer composites depended on the properties and nature of fillers such as functionality, polarity, specific surface area, filler loading and time in water [94]. The results demonstrate that the water absorption of NR–B, NR–BC, NR–T, NR–TC and NR–W increase with increasing filler loading content, due to the hydrophilic nature of silica and other metal oxides, which are the main components in three types of ashes. The water uptake rates of the composite NR films filled with BRHA, BRAHT and WRHA were higher, as compared to NR film, and the saturation point was reached after the immersion in water for 2 days. The fillers, BRHA, BRHAT and WRHA, are polar compounds and contain hydroxyl groups from silica and other metal oxides. The surface hydroxyl groups on metal oxides are sites for the absorption of water molecules by hydrogen bonding. Thus, the increased RHA loading content promoted WAC of the composite films. Metal content in BRHAT was lower than BRAH and WRHA resulted in higher WAC than NR–BRHA and NR–WRHA composites. NR composite filled with RHA was previously reported [95, 96]. Without the  $\text{CaCl}_2$  crosslinking process, the composite film filled with WRHA demonstrated higher WAC than that filled with BRHA, which is likely due to the higher amount of  $\text{SiO}_2$  in WRHA, as compared to BRHA. The maximum WAC at around 78% was obtained from NR–W films at WRHA loading content of 100 phr.

**Figure 4. 12** Water absorption capacity of NR, NR–B, NR–BC (a), NR–T, NR–TC, NR–TS (b) and NR–W, NR–WC, NR–WS (c).

The treatment by  $\text{CaCl}_2$  had different effects on the WAC of the NR composites filled with BRHA, BRHAT and WRHA. The  $\text{CaCl}_2$  crosslinked NR–WC showed considerably enhanced resistance for water uptake, especially at high WRHA loading content of 60 and 100 phr (Figure 4.12c). The water uptake of NR–WC at WRHA loading 100 phr was reduced to 11%, which was only  $\approx 1/7$  that of NR–W100 and was only  $\approx 1/4$  that of NR film. Previously, a significant reduction in water solubility of crosslinked alginate-based films by 1%  $\text{CaCl}_2$  was reported [87]. It was suggested that the crosslinking alginate by  $\text{CaCl}_2$  generated an “egg box” network. The  $\text{COO}^-$  in the alginate binds to the  $\text{Ca}^{2+}$ , resulting in reduced available alginate chains to bind with  $\text{H}_2\text{O}$  molecules. The crosslinking NR–W composites by  $\text{CaCl}_2$  could also increase filler–rubber interactions and limited water diffusion into the NR–W composites. Accordingly, NR–WC presented lower WAC after crosslinking by  $\text{CaCl}_2$ . On the other hand, the WAC of NR composite films filled with BRHA and BRHAT were increased after crosslinking by  $\text{CaCl}_2$  (Figure 4.12a, b). As previously discussed in the noneffective alginate crosslinking by  $\text{Ca}^{2+}$  of NR–BC and NR–TC composite films, in this case, the addition of  $\text{CaCl}_2$  was found to reduce filler–rubber interaction in NR–BC and NR–TC composites. The available  $\text{COO}^-$  in alginate molecule and  $\text{OH}^-$

in silica oxides could interact with water molecules, leading to higher water absorption of NR-BC and NR-TC. The addition of  $\text{CaCl}_2$  might also increase hydrophilicity of the films and, therefore, increase the water diffusion into NR-BC and NR-TC films. The effect of different crosslinking agents, WAC of NR composites with sulfur vulcanized was the lowest comparing with WAC of NR composite with/without crosslinking by  $\text{CaCl}_2$  at same filler loading. These results indicated sulfur vulcanized can reduce WAC of NR composites due to stiffer and stable structure of vulcanized NR films resulting in less penetrable by water molecules [97].

#### 4.7 Toluene Uptake

The results of the toluene uptake of NR and NR composite films soaked in toluene for 8 h are shown in Figure 4.13. The maximum toluene uptake of NR film was 1746% at the immersion in toluene for 4 h; after that, the film was decomposed in toluene. Toluene and NR are nonpolar; thus, this solvent can be highly absorbed in NR film. The high uptake rate and poor chemical resistance to nonpolar solvents of uncured NR were previously reported [51, 77, 96]. Uncrosslinked NR chains can dissolve in toluene, and the decrease in the solvent uptake of NR composites may reveal good filler-rubber interaction [96]. The toluene uptake rate of NR-B, NR-T and NR-W composites at RHA loading of 20 phr was much less than that of NR film; however, after the immersion in toluene for 4 h, both NR-B, NR-T and NR-W were, to some extent, decomposed in toluene. Uncured NR composites might be dissolved in nonpolar solvents, such as toluene [98]. More resistance to toluene uptake was observed in the NR composites with higher BRHA, BRHAT and WRHA content. The toluene uptake of the composite films decreased with increased filler loading and was considerably lower, as compared to that of pure NR film [51, 93]. The low toluene uptake of NR-B, NR-T and NR-W films was exhibited at RHA loading of 60–100 phr, which represented about 260–300% (or 0.15–0.17 of that of the NR film), due to polar nature of silica oxides, the major constituent in three types of RHAs. The integration of polar fillers into NR matrix can reduce the toluene uptake rate and absorption capacity. In addition, the NR composites filled with BRHA/WRHA at 60–100 phr maintained their structural stability during immersion in toluene for 8 h. This observation indicates that the composite films had good dispersion of RHA in the NR

matrix. After crosslinking by  $\text{CaCl}_2$ , the NR composites filled with WRHA, BRHAT, BRHA demonstrated slightly improved resistance to toluene. The toluene uptakes of NR-BC, NR-TC and NR-WC were reduced to 170–180%. The crosslinked films had better stability in toluene, as no decomposition of the films was observed during immersion in toluene for 8 h. Thus, the  $\text{CaCl}_2$  treatment seems to improve the solvent resistance of composite films. The addition of calcium ions into NR matrix possibly makes the surface more hydrophilic, resulting in lower diffusion of nonpolar solvent into NR matrix. The lowering of toluene uptake might also be attributable to the good interaction between filler and NR matrix [99]. Sulfur vulcanized NR composites present low toluene uptake that close to toluene uptake of NR composite with/without crosslinking by  $\text{CaCl}_2$  at filler loading 100 phr. These results indicated sulfur vulcanized can improve resistance of nonpolar solvent uptake of NR composites. The structural stability of NR composites was improved because the rubber chain motions were restricted by sulfur vulcanized and addition of RHA.

**Figure 4. 13** Toluene uptake of NR, NR–B, NR–BC, NR–BS (a), NR–T, NR–TC, NR–TS (b) and NR–W, NR–WC, NR–WS (c).

#### 4.8 Biodegradation in Soil

The preliminary study of biodegradation in soil of pure NR film and NR composite films filled with RHAs was determined in uncontrolled conditions (with an average temperature of  $\approx 30$  °C). The percentage weight loss and the visual analysis of the biodegraded samples after 1, 2 and 3 months are shown in Figures 4.14 and 4.15, respectively. The weight loss of the pure NR film was lower than all NR composite films at any degradation time, due to the slow degradation of NR in natural environments by microorganisms [100].

After 3 months, the weight loss of NR, NR–BRHA, NR–BRHAT and NR–WRHA were 5.3%, 7.6–13.0%, 5.3–14.5% and 7.6–18.4%, respectively. Overall, the NR–BRHA and NR–BRHAT composite presented comparable weight loss to NR–WRHA composites at similar RHA loading contents, except for the NR composites with 100 phr RHA loadings, of which, NR–W100 demonstrated relatively higher biodegradability in soil. The weight loss of composites increased with increased filler loading in all conditions. These results agree with those of Ramasamy et al. [101], who reported that the weight loss percentage of NRL foam increased with increased rice husk powder, because, at lower rice husk powder loading in foam composite, microbial activity was not high due to lack of microbial growth supports.

**Figure 4. 15** The visual analysis of biodegradation in soil of pure NR, NR-BC, NR-WC, NR-TC, NR-BS100, NR-TS100 and NR-WS100 for 3 months.

The effect of the  $\text{CaCl}_2$  treatment of the NR composites was observed from the composites at filler loading of 100 phr in both cases but in opposite directions. The weight loss of NR-BC100 and NR-TC100 were higher than that of NR-B100 and NR-TC100, respectively, whereas the weight loss of NR-WC100 was lower than NR-W100. These results are in accord with those on the water absorption capacity, which can be explained by the high number of fillers in NR matrix generating hydrophilic surfaces, resulting in enhanced water absorption of the composites. The higher water content in NR matrix could promote microbial activities that increase the rate of degradation [83, 102]. The weight loss of NR-WC100 was lower than NR-W100, because the  $\text{CaCl}_2$  crosslinked film displayed a higher tensile strength with lower WAC, as compared to NR-W100. On the other hand, the weight loss of NR-BC 100 was higher than NR-B100 and the weight loss of NR-TC100 was

higher than NR–T100, due to the higher WAC of the composite after  $\text{CaCl}_2$  crosslinking, as discussed earlier. It was also suggested that the use of sodium alginate as a dispersing agent in NR composites could increase the rate of biodegradation of the composites [92]. In addition, the weight loss of sulfur vulcanized NR composites was the lowest when comparing to composites with/without crosslinking by  $\text{CaCl}_2$  that could attribute to high tensile strength, stable structure and low WAC properties of vulcanized NR composites with RHA.

Figure 4.15 presents visual analysis of the biodegradation of NR and NR composite films during a period of 1–3 months. The enhanced degradation of NR composite films filled with higher RHA loading was clearly observed, especially at 3 months of biodegradation in soil. Black spots were found in the composite films reinforced with WRHA, while white spots, as well as fogging on film surfaces, were observed after 1 month in soil, indicating soil microflora activities in the composites, which is a good indicator of biodegradation [103]. Moreover, after 3 months in soil, some parts of the composite films disappeared. The results revealed that NR–BRHA, NR–BRHAT and NR–WRHA could be biodegradable in soil.

## 4.9 Electrical Properties

### 4.9.1 Dielectric properties

Dielectric properties of materials are important characteristics for predicting behavior with respect to application in electronic materials, such as print circuit boards, power transformers, microelectronics, radio propagation, remote sensing and actuator applications [9]. The dielectric properties of polymers depend on cations, dipole moment and space charge polarizations [104]. On the other hand, dielectric behavior of composite materials depends on dielectric properties of the matrix and filler, chemical composition, structure, shape and morphology of particles and filler dispersion in the composite [105]. The dielectric constant is the amount of energy from an external electrical field stored in materials. The dielectric constant of NR–BRHA, NR–BRHAT and NR–WRHA composites at different filler loadings are presented in Figure 4.16. The frequency dependence of the dielectric constant at ambient temperature was analyzed. The NR film had a low dielectric constant, in the range of 1.8–2, attributable to the nonpolar nature of NR, which has only

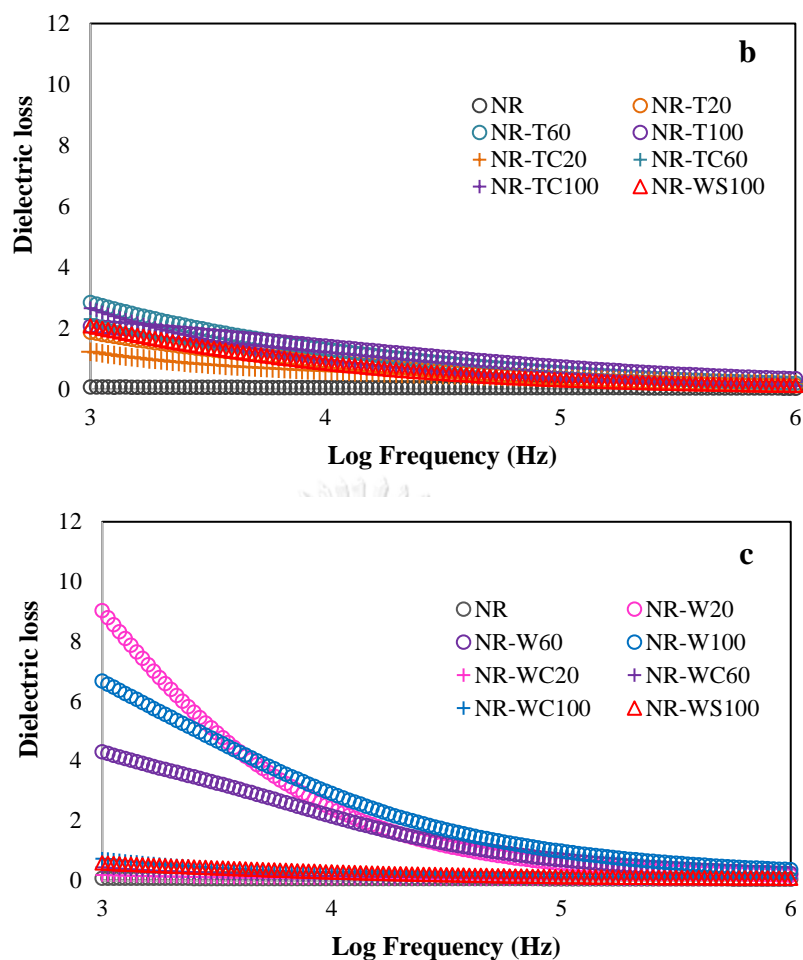

instantaneous electronic and atomic polarization [70]. It was demonstrated that the dielectric constant of the NR composite films filled with RHAs increased with increased BRHA, BRHAT and WRHA loading at all frequencies. BRHA, BRHAT and WRHA contained 87, 90 and 95% silica oxides with polar hydroxyl groups of silanol (Si–OH) on surface. Silica as a dielectric metal oxide semiconductor has a dielectric constant of about 3–9, and it has been used in micro- and nano-electronic industries [13]. Thus, the increase of RHA in NR composites resulted in higher dipole or orientation polarization; thus, the dielectric constant was enhanced [70]. In addition, the increase in RHA loading resulted in an increased space charge, leading to polarization in the composite matrix [57]. It was shown that the NR composite films presented a higher dielectric constant at lower frequencies. At high frequency, molecular movements arrested or decreased orientation polarization that leads to the decreased value of the dielectric constant [57, 106]. The dielectric constants of NR–BRHA were relatively higher than those of NR–BRHAT and NR–WRHA, which should be due to the higher degree of crystallinity of BRHA, as compared to that of WRHA. Correlations between crystal structure and dielectric properties of metal oxides were reported [107]. Dielectric constant of NR–BRHAT composites was lower than NR–BRHA and NR–WRHA could attribute to lower metal impurities content in BRHAT after treatment by acid washing. Metal and carbon-based filler could be acting as charge centers and increasing segmental mobility in the polymer matrix, which would enhance the dielectric constant of composites [108, 109]. Oxides are suggested as promising materials in high dielectric materials, as they possess both high dielectric constants and large band gaps [107].

**Figure 4. 16** Dielectric constant of NR, NR–B, NR–BC, NR-BS (a), NR, NR-T, NR-TC, NR-TS (b) and NR, NR–W, NR–WC, NR-WS (c)

The crosslinking of the composite films by  $\text{CaCl}_2$  caused a considerable drop in dielectric properties in all cases. The addition of  $\text{CaCl}_2$  might reduce the amount of electron charges, including  $\text{COO}^-$  (from alginate) and  $\text{OH}^-$  (from silica), in the composite films. The higher number of free protons suggests more localization of charge carriers along with mobile ions, resulting in higher dipole polarization and a higher dielectric constant [106]. For this reason, the value of the dielectric constant of composite film after crosslinking alginate was much lower than that of films without  $\text{CaCl}_2$  treatment. The obtained values for the dielectric constants of the films from the lowest value to the highest value were  $\text{NR} < \text{NR-TC} < \text{NR-WC} < \text{NR-BC} < \text{NR-T} < \text{NR-W} < \text{NR-B}$ . These results could also imply that low metal impurities content in BRHAT resulted in reducing segmental mobility in the polymer matrix. Moreover, the stronger interactions between WRHA filler and NR matrix could lower the hydrophilicity and polarity of the composite films. In case of sulfur vulcanized crosslinking, dielectric constant of NR-WS, NR-BS and NR-TS was lower than dielectric constant of uncrosslinking NR composites with RHA. These results indicated that high tensile strength of vulcanized NR film resulted in low dielectric constant of NR composites with RHAs. A similar effect from the reinforcement that caused the reduction of orientation polarization and the dielectric constant was previously reported [70].

**Figure 4. 17** Dielectric loss of of NR, NR-B, NR-BC, NR-BS (a), NR, NR-T, NR-TC, NR-TS (b) and NR, NR-W, NR-WC, NR-WS (c)

The dielectric loss factor presents the amount of energy loss from a material due to an external electric field [14]. The frequency dependence of dielectric loss of composites is shown in Figure 4.17. The values of dielectric loss demonstrate similar trends as those of the dielectric constant, which increased with increased filler loading and declined with increases in frequency. The increase of RHA loading enhanced the polar groups in the composite films, which led to enlargement of orientation polarization and relaxation in composite, resulting in relatively high energy loss [57]. In addition, increasing amorphous phase to the composite enhanced the flow of current through the amorphous region and generated amorphous phase relaxation, resulting in higher dielectric loss [70, 110]. At low frequency, dielectric loss was high, because of interfacial polarization enhanced by the difference between the

conductivity of various phases [57]. This result agrees with the previous work by Jamal et al. [109], in which the dielectric loss of nickel–rubber nanocomposites was high at frequency lower than  $10^5$  Hz, due to relaxation time of pure rubber enhanced when nickel nanoparticles were incorporated into the matrix. Moreover, the results indicate dielectric loss factor of NR–WC composites was lower than that of other composites at all WRHA loadings ( $\sim 0.7$ – $2.1$  at frequency  $10^3$  Hz). The effect of crosslinking composite by  $\text{CaCl}_2$  and sulfur vulcanized on the reduction of the dielectric loss factor was the same as that on the dielectric constant for similar reasons. Less free space in the matrix resulted in a low dielectric loss factor [106].

#### 4.9.2 Electrical conductivity

The improved electrical conductivity by adding fillers in nonconductive biopolymeric matrixes is a simple and efficient method to produce electrically conductive multifunctional biopolymer composites, while maintaining the low cost, biocompatibility, biodegradation and processability of the initial material. Figure 4.18 illustrates electrical conductivity of NR, NR–BRHA, NR–BRHAT and NR–WRHA composites with different crosslinking agent and filler loading. Neat NR film exhibited low electrical conductivity about  $2.1 \times 10^{-15}$   $1/\Omega \cdot \text{cm}$ . Generally, electrical conductivity of elastomers was less than  $10^{-12}$   $1/\Omega \cdot \text{cm}$  [111]. The results from Figure 4.18 indicated that electrical conductivity of NR-composites with three types of RHAs loading had a similar trend as observed from that of dielectric constant and dielectric loss. Electrical conductivity of NR–W was larger than NR–B and NR–T at RHA loading at 20 and 60 phr, whereas at filler loading at 100 phr, the electrical conductivity of NR–B was higher than NR–W and NR–T composites, respectively. These results could attribute to different compositions in three types of RHAs. BRHA composed of larger amount of metal and carbon than BRHAT and WRHA. Metal and carbon-based filler could create conductive path in NR matrix for electron transport [62]. It was demonstrated that the electrical conductivity of the NR composite filled with BRHA increased with increased BRHA loading. Electrical conductivity of NR–WRHA increased with increasing WRHA loading until the filler loading at 60 phr. However, it was found that the further loading of WRHA up to 100 phr caused the decrease in electrical conductivity of NR–W and NR–WC composite films. The main

composition of WRHA is silica, which is a poor conductor of electrons (electrical conductivity of silica was of about  $5 \times 10^{-14}$   $1/\Omega\cdot\text{cm}$  at  $300^\circ\text{C}$  [112]); thus, at WRHA loading of 100 phr, large amount loading of silica was integrated in NR matrix. The high silica content in the film did not increase conductive path for electrons, but resulted in the reduction of electrical conductivity. The maximum electrical conductivity of NR-B was  $4.9 \times 10^{-9}$   $1/\Omega\cdot\text{cm}$  at BRHA loading 100 phr and maximum electrical conductivity of NR-W and NR-T were  $4.0 \times 10^{-9}$  and  $7.8 \times 10^{-10}$   $1/\Omega\cdot\text{cm}$ , respectively.

Effect of crosslinking of the composites indicated similar trend as that observed from the dielectric properties. The crosslinking of the composite films by  $\text{CaCl}_2$  and sulfur vulcanize caused a reduction in electrical conductivity in all cases. The addition of  $\text{CaCl}_2$  might reduce the amount of electron charges, including  $\text{COO}^-$  (from alginate) and  $\text{OH}^-$  (from silica), in the composite films. Ionic groups such as  $\text{COO}^-$  that could help in the movement of the electrons throughout the polymer chain resulted in higher electrical conductivity of uncrosslinking NR composites with RHAs [113]. The electrical conductivity of sulfur vulcanized NR-BS was almost the same as that of NR-WS, which were  $6.0 \times 10^{-11}$  and  $6.9 \times 10^{-11}$   $1/\Omega\cdot\text{cm}$ , respectively; whereas the electrical conductivity of vulcanized NR-TS was about  $2.7 \times 10^{-11}$   $1/\Omega\cdot\text{cm}$ . Reduction of electrical conductivity of vulcanized NR-composites reinforced with RHAs could be owing to sulfur crosslinking in NR matrix. The double bonds in carbon-based polymers allow electric flow or transport that could increase electrically conductive in polymer matrix [114, 115]. Sulphur atoms in vulcanization process catch rubber molecules chain at the carbon-carbon double bonds and form C-S-S-C crosslink between the rubber molecules. After vulcanization, double bond in rubber molecules was replaced by sulfur atom that might be caused of decreasing of electrical conductivity in vulcanized NR composites with RHAs.

**Figure 4. 18** Electrical conductivity of NR, NR–B, NR–T and NR–W composites with different crosslinking agent and filler loading

## CHAPTER V

### **Bacterial cellulose reinforced with skim/fresh natural rubber latex for improved mechanical, chemical and dielectric properties**

#### **5.1 Introduction**

Globally, the level of plastic waste pollution from fossil resources and non-biodegradable polymers has been increasing in recent years; as a result, biopolymers have attracted considerable attention in reducing plastic pollution. Natural biopolymers, produced by plants and several microorganisms, tend to be biodegradable, meaning that they can degrade from exposure to bacteria in soil, compost, or marine sediment [116]. The most widely used biomaterials from natural biopolymers include natural rubber, starch-based materials, cellulose-derived polymers and bacterial cellulose composites. However, biopolymers generally present poor mechanical properties, low chemical resistance, short fatigue life and limited processing capability in comparison to synthetic polymers [117]. Multiple studies interested in improving biopolymers have tested their reinforcement with filler, blending with other polymers and improvements in their production method. Biodegradable polymers can be used in many electronic applications such as flexible displays, sensors, actuators, optics, fuel cells, dielectrics, electromagnetic shielding, piezoelectrics, insulators, (semi) conductors and microwave absorbers [118].

Bacterial cellulose (BC) is an organic compound produced by several bacterial strains in the form of a gelatinous and translucent membrane [119]. BC possesses an interesting 3D nanofiber network structure and displays outstanding physical and chemical properties, including high crystallinities and hydrophilicity, high tensile strength, high water holding capacity, non-toxicity, high purity (absence of lignin and hemicellulose), biodegradability and liquid and gas permeability [120]. BC can be used for applications in the pharmaceutical industry, food packaging, battery separators, adsorbents, cosmetics, biomaterials, electrical conductors or magnetic materials, biomedical materials and scaffolding for tissue engineering [121, 122].

Natural rubber (NR) is one of the most important polymers produced by plants and is widely utilized as raw material for many products due to its excellent flexibility. NR has been used for applications such as vehicle tires, condoms, gloves,

health equipment and accessories, coatings, shoe soles and medical products. Natural rubber latex (NRL) is extracted from a tree called *Hevea brasiliensis* in the form of a colloidal latex of cis-1,4-polyisoprene. Generally, fresh natural rubber latex (FNRL) is composed of about 30-40 wt% dry rubber content (DRC), 1.5-2 wt% protein, 1.5 wt% carbohydrate and 1.3 wt% lipid. FNRL is commonly preserved by adding ammonia and then being centrifuged to obtain concentrated natural rubber latex (CNRL) with about 60 wt% DRC. Skim natural rubber latex (SNRL) is the leftover suspension obtained from the centrifugation process as a low-cost by-product or as waste in some small factories. SNRL is composed of a small amount of rubber particles of about 4-6 wt% DRC with a large amount of non-rubber components. The non-rubber components in SNRL contain mostly water and approximately 3.2 wt% proteins, 0.4 wt% lipid and 3.1 wt% carbohydrates/sugars [123-125]. Typically, SNRL is used to produce skim blocks, skim crepe and lower grade products such as car mats, bicycle wheels, push cars and castors.

*Hevea* latex shows a bimodal particle size distribution, which can be classified into small rubber particles (SRP: particle size between 10 and 250 nm) and large rubber particles (LRP: particle size between 250 nm and 3  $\mu$ m) [17, 18, 126]. SNRL contains 81 wt% of SRP and 19 wt% of LRP, whereas FNRL is composed of 24 wt% of SRP and 76 wt% of LRP. SRP and LRP have different particle sizes and branch point structures, leading to the different characteristics and properties of SNR and FNR films [17, 20].

Recent research has focused on the dielectric properties of biopolymer composites, which are a key parameter in predicting the behavior of electronic materials. Natural fibers have also been of growing interest in electrically conductive polymer composites due to their inherent polar and hydrophilic nature [127, 128]. Previous research has studied the dielectric properties of natural fibers with polymers. The dielectric constant of polycarbonate-coated natural fabric *Grewia tilifolia* was  $7.3 \times 10^{-6}$  at 100 Hz and 30°C [128]. For polyaniline-coated nano-cellulose fiber/polyvinyl alcohol composites, the dielectric constant was  $1.3 \times 10^8$  at 40 Hz and room temperature [129]. From the previous data, BC appears to exhibit potential for usage in multiple applications, but one disadvantage is its low breaking elongation. NR possesses excellent elastic properties. However, to date, there have been very few

reports of a composite film of NR incorporated into BC matrices. In addition, no reports on composite films of cellulose filled with SNR and FNR have been documented so far. In our previous work, suitable conditions for the incorporation of concentrated natural rubber (CNR) to BC matrices was at 2.5% DRC of CNR concentration at an immersion temperature of 50°C. CNR-BC film from this condition exhibited high structural and thermal stability and favorable mechanical properties [130].

In Chapter IV, rice husk ash (RHA), which was a byproduct from burning rice husk (a cellulose-based fibrous material), was successfully used as filler in NR composite films. The NR-RHA composite films offer many advantageous properties, such as high mechanical properties, high chemical stability, significantly improved dielectric properties and biodegradability. According to the obtained properties, the composites offer potential for further development as stretchable conductive substrate or semiconducting polymer films for electronic applications. On the other hand, the study in Chapter V aims to use different types of NRL (SNRL and FNRL) as a filler to improve the mechanical, chemical and dielectric properties of cellulose matrix in form of BC. The effects of SNR and FNR concentrations and immersion temperature on the chemical, mechanical, biodegradation and dielectric properties of the composite films were investigated. The obtained results could be useful for the development of BC composite films filled with NR as a potential substitute for the existing substrate materials used in electrical insulators, electronic packaging and flexible electronic devices

## 5.2 Experimental

### 5.2.1 Materials

The stock culture of *Acetobacter xylinum* bacterial strain AGR 60 was supplied by Pramote Tammarat, the Institute of Food Research and Product Development, Kasetsart University, Bangkok, Thailand. Skim natural rubber latex (SNRL) and fresh natural rubber latex (FNRL) were supplied by Rubber Technology Research Centre (RTEC), Faculty of Science, Mahidol University, Nakhon Pathom, Thailand. SNRL and FNRL contained about 5% and 30% dry rubber content (DRC), respectively. Sucrose and ammonium sulfate were purchased from Ajax Finechem Pty Ltd (New South Wales, Australia). Acetic acid was purchased from Mallinckrodt Chemicals (Paris, KY, USA).

### 5.2.2 Film preparation

Bacterial cellulose (BC) pellicle was prepared by biosynthesis using coconut water as a based substance. The coconut water medium was mixed with 0.5% (w/v) ammonium sulfate, 5.0% (w/v) sucrose, and 1.0% acetic acid solution (30%, v/v) and sterilized at 110°C for 5 min. Precultures were prepared by a transfer of 15 mL stock culture to 300 mL in 500 mL Erlenmeyer flask and incubated statically at 30°C for 7 days. The sterile medium (60 mL) was added by *A. xylinum* stock culture (3 mL) in a sterile petri dish and statically incubated at 30°C for 7 days. The BC pellicles were purified by washing with deionized water (DI) for 30 min and, then treated with 1% (w/v) sodium hydroxide solution at room temperature for 24 h remove bacterial cells, washed with running water for 30 min and then rinsed with deionized (DI) water until the pH reached 7.

The procedure for the preparation of BC reinforced with SNR-BC and FNR-BC films were developed from Potivara and Phisalaphong (2019) [130] as follows. SNRL and FNRL were diluted with DI water to form 50 ml SNRL and FNRL suspensions of 1%, 2.5% and 5% w/v. BC pellicle was then immersed in SNRL and FNRL suspension for 48 h as the immersion temperature varied between 50 and 60°C. Then, they were washed with DI water, air-dried at 30°C for 48 h, and stored in plastic film at room temperature. BC was defined as the unmodified BC and SNR-BC and FNR-BC were defined as the modified BC by immersing in SNRL and FNRL

suspension, respectively. The xSNR–BCy or xFNR–BCy films were defined as the modified BC by immersing in SNRL and FNRL suspension at x% DRC and at an immersion temperature of y °C. For example, 1SNR–BC50 was the BC film modified by immersing in an SNR suspension at 1% DRC and at a temperature of 50 °C.

### 5.2.3 Characterizations

#### *Morphologies of composites*

Morphologies of neat BC, SNR, FNR, SNR-BC and FNR-BC composite films were observed by Scanning Electron Microscope and Energy Dispersive X-ray Spectrometer SEM-EDS (IT-500HR) using a JEOL, JSM-IT-500HR and JEOL, JED-2300 (Tokyo, Japan). The specimens were frozen in liquid nitrogen and vacuum dried. After that, the specimens were sputtered with gold. The SEM-EDS instrument was performed at an accelerating voltage of 10 kV. The average thickness of the dried BC, SNR, FNR films and BC composite films was measured using the Image J program.

#### *Rubber and protein contents in NRL*

The protein content of rubbers was determined by the analysis of nitrogen content using a LECO FP-258 nitrogen analyzer where the dried rubber sample (ca. 0.25 g) was accurately weighed and then subjected to combustion in an oxygen atmosphere. The measurement was repeated three times to obtain the average nitrogen content of each rubber sample. The nitrogen content estimate was multiplied by a factor of 6.25 to the equivalent amount of protein.

#### *The functional groups and chemical structure*

The functional groups and chemical structure of films were determined by Fourier Transform Infrared (FTIR) Spectroscopy (PerkinElmer, Waltham, MA, USA) in the ranges of 4000-650  $\text{cm}^{-1}$  with a resolution of 4  $\text{cm}^{-1}$ .

### ***Mechanical properties***

For mechanical properties tests of dry films of BC, SNR, FNR, SNR-BC and FNR-BC composites (Young's modulus, tensile strength, and elongation at break) were performed using Universal Testing Machine (Instron, Norwood, MA, USA). The tests were determined according to ASTM D882. At least five specimens for each different blend composition were tested and the average of the results has been taken.

### ***Water absorption capacity***

The measurement of water absorption capacity (WAC) was performed by using the specimen films with dimensions of  $2 \times 2$  cm<sup>2</sup>, with the thickness of 0.04-0.12 mm. The specimens were immersed in distilled water at room temperature for 0-16 days. The specimens were removed from water every 2 days and excess water at the surface of the samples was blotted by Kimwipes® paper. The weight of wet sample was measured. All testing was carried out in triplicate. Water absorption capacity was calculated by using the formula:

$$\text{Water absorption (\%)} = \frac{W_h - W_d}{W_d} \times 100$$

where,  $W_h$  and  $W_d$  are the weights of the hydrated and dried specimens, respectively.

### ***Toluene uptake***

For the test of toluene uptake, dried sample films of  $2 \times 2$  cm<sup>2</sup>, with the thickness of 0.04-0.12 mm were immersed in toluene at room temperature. The weight change was monitored at 1 h intervals for 8 h. All testing was carried out in triplicate. Toluene uptake was calculated by using the formula:

$$\text{Toluene uptake (\%)} = \frac{W_t - W_d}{W_d} \times 100$$

where,  $W_d$  and  $W_t$  are the weights of the specimens before and after immersion at a time (t), respectively.

### ***Biodegradation in soil test***

For the test of biodegradation in soil, each test specimen having 5x5 cm<sup>2</sup>, with the thickness of 0.04-0.12 mm was used for the measurement of biodegradation in soil. Potting soil purchased from a garden center (Bangkok, Thailand) was used for the experiment, the main compositions of potting soil were loam soil, compost manure and coconut coir. The moisture content of the soil was around 50-60 wt%. The specimens were weighed and buried in soil for 6 weeks the depth of 10 cm for 6 weeks under ambient condition, where the temperature range was 24 to 35°C. After 2, 4 and 6 weeks, the samples were removed from soil, washed with DI water, dried at 40°C for 12 hours and recorded for their weights. The degradation was evaluated by measuring the weight loss by using the formula:

$$\text{Biodegradation (\%)} = \frac{W_0 - W_t}{W_0} \times 100$$

where,  $W_0$  and  $W_t$  are the initial dry weight of the films (time = 0) and the residue dry weight of films after biodegradation in soil (time = t), respectively.

### ***Dielectric properties***

The dielectric constant and dielectric loss factors were measured directly by using impedance analyzer with a precision impedance analyzer (Agilent 4294A, USA) at room temperature. The measurements were done at varying frequencies ranging from 10<sup>2</sup>-10<sup>5</sup> Hz. The samples were coated by silver paint as electrode on both sides before measurement.

#### ***Dielectric constant***

The dielectric constant of a material is defined as the ratio of the capacitance of a condenser containing the material to that of the same condenser under vacuum. The capacitance of a condenser measures the extent to which it can store charges. Dielectric constant can determine by using the following equation:

$$\varepsilon' = \frac{Cd}{E_0A}$$

Where  $\varepsilon'$  is dielectric constant, C is capacitance, A is surface area of sample, d is thickness of sample, and  $E_0$  is dielectric permittivity ( $8.85 \times 10^{-12}$  Farad.m<sup>-1</sup>).

#### *Dielectric loss ( $\varepsilon''$ )*

The electrical loss or the amount of energy dissipated by the insulating material when the voltage is applied to the circuit can be represented by means of a dissipation factor. Most of the elastomers have lower dissipation factor at room temperature. The loss factor (dielectric loss,  $\varepsilon''$ ), the dielectric constant ( $\varepsilon'$ ) and the dissipation factor ( $\tan \delta$ ) are related by the following equation:

$$\tan \delta = \frac{\varepsilon''}{\varepsilon'}$$

#### *Electrical conductivity*

The electrical properties were measured and obtained using an impedance analyzer with an LCR meter. The measured electrical resistivity of the composite materials was converted into electrical conductivity by using the following equation:

$$\rho = \frac{RA}{L} = \frac{1}{\sigma}$$

Where  $\rho$  is the volume resistivity ( $\Omega\text{m}$ ),  $R$  is the resistance ( $\Omega$ ),  $A$  is the cross-section discs (m<sup>2</sup>),  $L$  is the thickness (m), and  $\sigma$  is the electrical conductivity ( $\Omega\text{m}$ )<sup>-1</sup>.

## 5.3 RESULTS AND DISCUSSION

### 5.3.1 Composition of SNRL and FNRL and morphology of BC, SNR, FNR and composite films

The SNRL was light brown in color, whereas FNRL appears as a milky white suspension (Figure 5.1a). NRL presents a bimodal particle size distribution of small rubber particles (SRP) (10 - 250 nm) and large rubber particles (LRP) (250 nm - 3  $\mu$ m) [17, 130]. SNRL contains SRP: LRP in a ratio of  $\sim$  4:1, while FNRL contains SRP: LRP in a ratio of  $\sim$  1:3 [17]. The main components of natural rubber latex (NRL) are rubber hydrocarbon, water and proteins and other non-rubber components. Proteins associated with the rubber molecules and/or particles usually present in term of nitrogen content in a rubber sample. Nitrogen contents of LRP and SRP were about 0.127 and 0.661%wt, respectively [17]. The dry rubber and protein contents of SNRL and FNRL are shown in Table 5.1.

**Table 5. 1** Dry rubber and nitrogen contents\* of SNRL and FNRL.

Sample	Dry rubber content (DRC) (% w/w)	Protein content (% w/w)
Skim natural rubber latex (SNRL)	8.01	18.50
Fresh natural rubber latex (FNRL)	36.68	4.75

\*measured in the dry form of SNRL and FNRL

**Figure 5. 1** Photographs of skim (SNRL) and fresh (FNRL) natural rubber latex (a) and dried BC, SNR and FNR films (b) and SNR-BC and FNR-BC composite films at different NRL concentrations (c)

The dried SNR film was dark brown in color with wrinkles on the film surface; on the other hand, the dried FNR film was white and transparent with a smooth surface. The dried film of BC was white with a smooth surface (Figure 5.1b). The photographs of the SNR-BC and FNR-BC composite films are shown in Figure 5.1c; the two different types of NR-BC composite film had a rather smooth surface, and the color of the films changed according to the concentration of SNRL/ FNRL. The SNR-BC and FNR-BC composites had a color and structure similar to BC at a low NR content. At a high concentration of SNRL and FNRL loading, the color of the composite films became more similar to the color of the dried SNR and FNR films, respectively.

The morphologies of the dried BC, SNR and FNR films are illustrated in Figure 5.2. The surface area of the never-dried BC film shows a coherent three-dimensional network of cellulose nanofibers of a highly porous system (Figure 5.2a). The diameter of BC nanofibers was about 40-100 nm and their pore size ranged between 0.2-2  $\mu\text{m}$ . A similar diameter and pore structure of an unmodified BC hydrogel were reported in previous studies [130, 131]. The surface area of dried BC shows a dense nanocellulose fiber layer. The nanofibers also appeared as crossed and randomly oriented, as shown in Figure 5.2b. A cross section of the dried BC film presents multilayers of thin sheets (Figure 5.2c). The shrinkage and compact of the BC structure was attributed to evaporation of water in BC during the drying process.

**Figure 5. 2** Scanning electron microscopy (SEM) images of surface morphologies of never dried films of bacterial cellulose (BC) (a) dried BC films: surface (b) and cross-section (c)

The morphologies of SNR-BC and FNR-BC composite films are illustrated in Figure 5.3. The surface area of the SNR-BC and FNR-BC composites indicated that BC films were integrated with SNRL and FNRL, as can be seen clearly in 5SNR-BC50 and 5FNR-BC50. The incorporation of SNR and FNR into BC nanofibers led to the reduction of BC film porosity. The cross section of dried 5SNR-BC50 and 5FNR-BC50 films presented densely packed nanocellulose fibers combined with SNR and FNR, respectively. The thickness of the composite films increased with increased concentrations of SNR and FNR. Overall, the thicknesses of the SNR-BC films were greater than the FNR-BC films.

**Figure 5. 3** SEM micrographs of surface morphologies (on the top) and cross-section (on the bottom) of dried films: 1SNR-BC50, 5SNR-BC50, 1FNR-BC50 and 5FNR-BC50.

The thickness and dry weight of BC composite films before and after the immersion in SNRL and FNRL suspensions are shown in Figure 5.4 and Figure 5.5, respectively. The thicknesses of both SNR-BC and FNR-BC composite films show a similar trend with a dry weight of composite films that relatively increase with an increased concentration of SNRL and FNRL loading, in the same way according to previous work [132] of BC films modified by loading of alginate gel. The highest thicknesses of SNR-BC and FNR-BC composites were obtained by the immersion in SNRL and FNRL suspension at 5% DRC (at 60 °C), which were a ~5.8-fold and ~3.1-fold increase over the unmodified BC film, respectively. The amount of

integration of SNR and FNR into BC was estimated from the change of the film's dried weight before and after immersion in SNRL and FNRL suspensions. The highest amount of SNR and FNR diffused and adsorbed into BC was observed at loadings of SNR and FNR at 5% DRC and 60 °C, where the amounts of SNR and FNR in the composite films were 86.7%, and 72.7%, respectively (the estimated ratios of SNR/BC and FNR/BC in the composite films were 6.5, and 2.7, respectively). Overall, the thickness and dry weight of SNR-BC films were higher than FNR-BC films in all conditions. The effect of immersion temperature on film thickness and dry weight showed a similar trend for both SNR-BC and FNR-BC composites. Increasing immersion temperature from 50°C to 60°C resulted in larger thickness and dry weight for SNR-BC and FNR-BC composites, which implied a larger amount of integration of SNR and FNR into BC. These results can be attributed to the fact that the increased immersion temperature increases SNR and FNR molecular motion and creates higher kinetic energy, resulting in a higher diffusion rate of SNR and FNR into the nanofiber network. Moreover, polymer chains become more flexible and free space between polymers increases at higher temperatures, which leads to enhanced diffusion [133]. Previously, modification of BC by immersion in concentrated natural rubber latex (CNRL) was studied, and the optimal conditions were reported at a concentration of 2.5%-5.0 % DRC and a temperature of 50°C to 60°C [130]. However, because CNRL contains mostly large NR particles, BC pellicles had to be immersed in a diluted CNRL suspension in the presence of a dilute aqueous solution of ethanol for enhanced diffusion [130].

**Figure 5. 4** Thickness of dried BC, SNR-BC and FNR-BC films modified by immersing in SNRL and FNRL suspension at various concentrations (0%-5% DRC) at temperature of 50 °C and 60 °C.

All results from SEM images and the thickness and dry weight of SNR-BC and FNR-BC composite films indicate that the diffusion and adsorption of SNRL into BC were greater than those of FNRL. These results can be attributed to the average particle size of SNRL and FNRL molecules. Previous studies reported that NRL from *Hevea brasiliensis* is typically comprised of a bimodal particle size distribution, with both small rubber particles (SRP,  $\phi \sim 10$  to 250 nm) and large rubber particles (LRP,  $\phi \sim 250$  nm to 3  $\mu\text{m}$ ) [126, 134]. SNRL consists of 81% wt. of SRP and 19% wt. of LRP, whereas FNRL consists of 76% wt. of LRP and 24% wt. of SRP [17]. Smaller rubber particles move more rapidly and easily diffuse through the pores of a BC network than larger rubber particles; therefore, the amount of SNR integrated into BC composites was larger than the amount of FNR integrated into BC composites.

**Figure 5. 5** Dry weight of BC composite films modified by immersing in SNRL and FNRL suspension at various concentrations (0%–5% DRC) at temperatures of 50 °C and 60 °C: the dry weight of BC (■); the estimated dry weights of SNR and FNR (■).

### 5.3.2 Fourier Transform Infrared (FTIR) Spectroscopy

The FTIR spectra of BC, SNR, FNR, SNR-BC and FNR-BC composites are shown in Figure 5.6. The FTIR spectrum of pure BC shows a broad peak of O–H stretching of the hydroxyl group at  $3340\text{ cm}^{-1}$  and at  $2919\text{ cm}^{-1}$ , corresponding to C–H stretching. The absorption band located at  $1107\text{ cm}^{-1}$  is attributed to C–O symmetric stretching [69, 77]. The SNR and FNR films show the principal peaks corresponding to cis-polyisoprene functional groups of NR. The asymmetric stretching vibration of methyl groups ( $-\text{CH}_3$ ) occurs at  $2960\text{ cm}^{-1}$  and C–H deformation occurs at  $1447\text{ cm}^{-1}$ , while the peaks observed at  $2927\text{ cm}^{-1}$  are assigned to the symmetric stretching vibration of methylene ( $-\text{CH}_2$ ), and C=C stretching is observed at  $1662\text{ cm}^{-1}$  [51, 130, 135]. The largest difference between the spectrum of the two NR types is that the principal peaks of proteins appear only within the spectrum of SNR. The broader peaks of around wavenumber  $3280\text{ cm}^{-1}$  are assigned to the N–H stretching (amino acids or dipeptides) of protein molecules in SNR, while

the peaks are observed at 1567 and 1630  $\text{cm}^{-1}$ , corresponding to N-H bending (amide II) and C=O stretching (amide I), respectively [125, 136, 137]. The FTIR results confirmed that the protein content in SNR was higher than FNR (18.50 wt% protein in SNRL and 4.75 wt% protein in FNRL as shown in Table 5.1). The intense broad band between 3200 and 3500  $\text{cm}^{-1}$  could also correspond to hydroxyl groups. The broad band of the hydroxyl group is more apparent in SNR than FNR, which indicates a higher hydroxyl content in SNR. It was suggested that the hydroxyl groups in SNR are raised from the hydration of proteins and phospholipids, which were chemically bound and could not be removed after drying [20]. The FT-IR spectra of the SNR-BC and FNR-BC films indicate characteristic peaks of both BC and NR without new peaks. Moreover, SNR-BC and FNR-BC composites show a similar spectra trend at different SNR and FNR concentrations. At low SNR and FNR concentrations (1% and 2.5% DRC), SNR-BC and FNR-BC composites exhibit spectra more similar to BC. Whereas, at a high NR loading (5% DRC), SNR-BC and FNR-BC composites display spectra more similar to SNR and FNR.

**Figure 5. 6** FTIR spectra of BC, SNR, FNR, SNR-BC and FNR-BC composite films.

### 5.3.3 Mechanical properties

Mechanical properties of dried films of BC, SNR-BC and FNR-BC were presented in terms of elongation at break, tensile strength and Young's modulus, as shown in Figure 5.7. SNR and FNR films used for mechanical testing were prepared from 50 mL of 5% DRC of SNRL and FNRL. The mechanical properties of pure SNR and FNR are shown in Table 5.2. It was revealed that the elongation at break and tensile strength of FNR were higher than those of SNR because the major component in the solid content of FNRL was polyisoprene (~30% DRC), with only a small amount of non-rubber components such as lipids, proteins and carbohydrates (~ 4.8 wt%). The solid content of SNR, on the other hand, was composed of a rubber content of about 3% DRC and 6.8 wt% of non-rubber components [124, 125, 137]. The large amount of LRP content in FNR resulted in high elongation at break and tensile strength. In addition, the Young's modulus of FNR was ~2.95 MPa, whereas the Young's modulus of SNR could not be determined due to the very low rubber content and the high concentration of non-rubber components in SNR films. BC has been reported as having a high tensile strength and Young's modulus, but low elongation at break. BC mechanical properties can vary depending on several factors such as culture processing conditions, bacterial strain used and drying processing conditions [130, 138-140]. As compared to SNR and FNR films, BC had lower elongation at break but revealed a considerably higher tensile strength and Young's modulus.

**Table 5. 2** Mechanical properties of SNR, FNR and BC films.

<b>NRL</b>	<b>Elongation at break (%)</b>	<b>Tensile strength (MPa)</b>	<b>Young's modulus (MPa)</b>
<b>SNR</b>	28.32 ± 1.37	0.35 ± 0.02	n.d*
<b>FNR</b>	136.43 ± 3.12	0.75 ± 0.03	2.95 ± 0.46
<b>BC</b>	1.48 ± 0.15	107.03 ± 7.38	11201.33 ± 521.37

\*n.d = cannot determine

Figure 5.7a clearly shows that the incorporation of SNR and FNR into BC resulted in improved elongation at break for both SNR-BC and FNR-BC composite films. The maximum elongation at break values of the SNR-BC and FNR-BC were 28.03% and 3.76%, respectively, from the immersion in 5% DRC of SNRL and FNRL at 60 °C. Compared with the unmodified BC film, the elongation at break was ~18.9-fold increase for SNR-BC and ~2.5-fold increase for FNR-BC. SNR-BC films exhibit significantly higher elongation at break than those of FNR-BC films. From the results of total dry weight (Figure 5.5), a higher amount of filler loading was obtained at the higher immersion temperature of 60 °C, especially at a high loading concentration at 5% DRC. Because NR possesses excellent elastic properties, this higher rubber content in composite films resulted in higher elongation at break for both SNR-BC and FNR-BC composite films. In addition, SNR and FNR coating on BC fibers could help fibers better absorb energy, prevent the fabric from breaking and help the fabric elongate longer before failure due to breaking [141]. It should be noted that the elongation at break of pure SNR film was lower than that of pure FNR film, but the elongation at break of SNR-BC was larger than FNR-BC films. This could be attributed to the larger amount of rubber loading into SNR-BC composite films (which could relate to the thickness or dry weight of composite films). In addition, the high protein content in SNRL might also have a positive effect on elongation at break. From the previous report, deproteinization of SNRL resulted in a decrease of elongation at break from 498.79% to 400.48% [125].

The tensile strength of SNR-BC and FNR-BC films are shown in Figure 5.7b. The composite SNR-BC film of 2.5SNR-BC50 presented the maximum tensile strength at 123.12 MPa, whereas the composite of 5FNR-BC50 presented the maximum tensile strength at 177.47 MPa. The tensile strength of FNR-BC increased with increasing FNR concentration; however, in the case of SNR-BC, tensile strength decreased with increased loading from 2.5 to 5%, which should be due to a high ratio of SRP particles in the composite film. The reinforcement effects on Young's modulus of BC composite integration with SNR and FNR were quite similar to those on tensile strength. The Young's modulus values of the composite films were significantly higher, as compared to those of pure SNR and FNR films, as shown in

Figure 5.7c. The maximum values of Young's modulus for SNR-BC and FNR-BC were obtained from 5SNR-BC50 (6.93 GPa) and 5FNR-BC50 (13.32 GPa). The neat BC film possessed excellent tensile strength and a high Young's modulus, whereas the SNR and FNR films have a low tensile strength and Young's modulus. By loading with SNR, the SNR diffused and combined with the BC network, resulting in a significantly higher elongation at break; however, the tensile strength changed slightly at a low SNR loading, but relatively decreased at a high SNR loading. Therefore, the Young's modulus of the SNR-BC composite films tended to decrease with the amount of SNR loading. These results agree with those reported by Urbina et al. [119], who presented the mechanical properties of BC/polyurethane nanocomposites prepared by immersing wet BC into waterborne polyurethane (WBPU) at different time intervals. It was reported that the amount of WBPU in the BC/WBPU nanocomposite increased with immersion time, and it was shown that while the Young's modulus and the tensile strength of BC/WBPU decreased, elongation of the composite increased with increased immersion time. In the present study, only the composite film of 5FNR-BC50 presented a significantly improved tensile strength and Young's modulus compared to the unmodified BC film. This result could indicate that the loading of FNRL (which contains a high content of LRP) promotes a higher mechanical strength of the composite BC films, whereas the loading of SNRL (which contains a high content of SRP and protein particles) could promote greater flexibility in the composite BC films. Rubber coated on BC fiber could prevent the fiber from resisting external work load force [141]. In addition, NR has a high structural regularity and tends to crystallize spontaneously when it is stretched [142].

The particle size of the rubber molecules had a strong effect on the mechanical properties of SNR and FNR films. From previous work on the strength of LRP and SRP [17], it was reported that the strength of LRP (8.2 MPa) was much greater than that of SRP (3.2 MPa). This is due to strain-induced crystallization caused by phospholipids in NR during stretching. Moreover, the higher strength of LRP might be attributed to the branch-point network formed by the coordination of phospholipids in the LRP [143]. SRP are composed of a high protein content but a low rubber content. The mechanical strength of SRP films was very low, which could relate to the proteins in SRPL that had no direct effect on the strength [127]. The majority of

FNR particles are LRP, whereas the majority of SNR particles are SRP; therefore, the tensile strength and Young's modulus of FNR-BC composites tends to be higher than SNR-BC composites.

The tensile strength and Young's modulus of both SNR-BC and FNR-BC films tended to decrease with the increase of the immersion temperature from 50 °C to 60 °C. At a higher immersion temperature, a larger amount of SNR and FNR was integrated into BC matrices and a higher collision rate and particle agglomeration could occur. The agglomeration of NR particles might cause the poor distribution of NR in BC matrices [130]. Moreover, it was previously reported that a temperature range between 58 °C to 60 °C produced the decomposition of branch points generated by the interaction of proteins and phospholipids of NR molecules [144]. It was revealed in the present study that the tensile strength and Young's modulus of SNR-BC and FNR-BC composite films, especially at high SNRL or FNRL loadings, decreased with the increase of the immersion temperature from 50 °C to 60 °C.

The reinforcement of BC with SNR and FNR prepared via immersion of BC in SNRL and FNRL considerably enhanced the elongation at break of the SNR-BC composites; these are considered very high compared to the BC composite reinforced by concentrated natural rubber (CNR: 60 % DRC), which presented a maximum elongation at break of the CNR-BC film of only 3.0%–3.5% at 2.5%–5% CNRL loading [130]. Previous studies have also reported the maximum tensile strength of NR composites at 100 MPa when reinforced with BC fibers at a BC loading of 80 wt.% [77], 6 MPa at a BC loading of 7 phr [145] and 24 MPa at a BC loading of 10 phr [146]. It was revealed that the tensile strength of NR composites reinforced with BC were lower than the composite films of BC reinforced with NR (SNR, FNR and CNR).

The comparison of mechanical properties of BC composites filled with different types of NR is shown in Table 5.3. The reinforcement of BC with SNR and FNR prepared via immersion of BC in SNRL and FNRL considerably enhanced the elongation at break of the SNR-BC composites. These are considered to be very high compared with BC composites reinforced by CNR, which presented a maximum elongation at break of 3.2%–3.5% at a concentration of 5% DRC. On the other hand, the Young's modulus and tensile strength of CNR-BC were higher than those of

SNR-BC and FNR-BC. These results could be attributed to the amount of LRP in BC composites, as the major NR particles in CNR were LRP (82 wt%) [17]. The film fabricated from CNRL has higher mechanical strength, in terms of tensile strength, than the films fabricated from FNRL and SNRL. In addition, LRP particles were more difficult to transfer and diffuse into the BC network than SRP particles; therefore, the amount of CNR in CNR-BC composites was lower compared to the amount of SNR and FNR in SNR-BC and FNR-BC composites.

**Figure 5. 7** Elongation at break (a), Tensile strength (b), and Young's modulus (c) of dried BC and NR-BC films modified by immersing in SNRL and FNRL suspension at various concentrations (0%–5% DRC) at temperatures of 50 °C and 60 °C.

**Table 5. 3** Comparison of the mechanical properties of BC composites loading with different types of NR particles.

### 5.3.4 Water Absorption Capacity

The results of the water absorption capacity (WAC) tests of BC, SNR, FNR, SNR-BC and FNR-BC composite films are presented in Figure 5.8. The WAC of BC was higher than the SNR, FNR and SNR-BC and FNR-BC composite films due to the hydrophilic nature of BC, which is composed of a high density of hydroxyl groups on its surface [147]. In addition, the hydrophilic nature of BC is attributed to the arrangement of BC fiber and the high surface area per unit of mass [138]. The water adsorption of BC film increased nonlinearly during a period of 0-4 days for a water uptake of 0–700%; afterwards, the water absorption slightly increased during immersion in water for 4-16 days. The maximum WAC of BC was about 809% at day 18. The WAC of SNR and FNR films was much lower than that of the BC, SNR-BC and FNR-BC composites due to the hydrophobic nature of NR. The WAC of SNR-BC and FNR-BC films decreased with increasing SNR and FNR concentrations due to the hydrophobic nature of rubber particles, which are the main components in NRL. The water uptake of 5SNR-BC50 and 5FNR-BC50 were reduced to ~187%, which was  $\approx 1/4$  that of neat BC film. At a low amount of SNR and FNR diffused into BC fiber, hydroxyl groups of cellulose were sites for the adsorption of water molecules via hydrogen bonding. At a larger amount of SNR and FNR integrated into BC fibers, small amounts of water could be adsorbed into SNR-BC and FNR-BC films. Thus, the water resistance of SNR-BC and FNR-BC films increased with SNR and FNR loading content in the films. Overall, the results demonstrated that the structural stability in water of the BC composite films was improved upon integrating SNR and FNR into BC matrices.

In addition, the WAC of the neat SNR film was slightly larger than the neat FNR film (the maximum WAC of SNR and FNR were 40% and 38%, respectively), and the WAC of SNR-BC films was slightly higher than FNR-BC composite films. Previous studies indicated that the core-shell of NR latex particles are made up of a hydrophobic core of polyisoprene surrounded by complex hydrophilic proteins and phospholipids [15, 148], and non-rubbers components in NRL can absorb water [149]. The major component of FNRL is rubber particles (polyisoprene), which have intrinsic hydrophobic properties, whereas proteins are one of the major components of SNRL. Therefore, the WAC of SNR and SNR-BC were relatively higher than that of

FNR and FNR-BC films. This agrees with a previous report by Danwanichakul and Than-ardna [150], which stated that SNR films were more hydrophilic than CNR films.

**Figure 5. 8** Water absorption capacity (WAC %) of BC, SNR, SNR-BC films (a) and BC, FNR, FNR-BC films (b).

### 5.3.5 Toluene uptake

The toluene uptake of BC, SNR, FNR and BC composite films determined by soaking films in toluene for 8 hours are shown in Figure 5.9. Toluene uptake of BC was lowest when compared to SNR, FNR, SNR-BC and FNR-BC films due to hydrophilic nature of BC. The maximum toluene uptake of BC was 17% at an immersion time of 8 hours. The toluene uptake for both the SNR and FNR films is shown in the insert Figures of Figures 5.9a and 5.9b, respectively. At the initial absorption, the toluene uptake of the SNR and FNR films rapidly increased and reached a maximum value at 4934% and 5449%, respectively, within 2 hours. After that, the SNR and FNR films were gradually decomposed in toluene. The toluene uptake of SNR and FNR films was much higher than BC and BC composite films due to the nonpolar nature of NR, which can highly absorb nonpolar solvents. The high uptake rate of nonpolar solvents of uncured NR was previously reported in several studies [51, 151]. The toluene uptake of both SNR-BC and FNR-BC were higher than that of the neat BC film, but much less than those of the SNR and FNR films. The toluene uptake of BC composites increased with an increasing SNR and FNR content in BC composite films. A larger amount of rubber content in BC matrices resulted in a higher absorption of nonpolar solvent by the films. The lowest toluene uptake of SNR-BC and FNR-BC films was detected from the composite films of 1SNR-BC50 and 1FNR-BC50, respectively, which were about 0.0053 and 0.0070 that of the SNR and FNR film, respectively. In addition, the toluene uptake of the SNR film was lower than that of the FNR film, and the toluene uptake of the SNR-BC films was lower than those of the FNR-BC films due to the greater hydrophilic protein content in SNRL compared to FNRL. The SNR-BC and FNR-BC composite films demonstrated significant improvements in resistance to toluene when compared with SNR and FNR films.

**Figure 5.9** Toluene uptake of BC, SNR, SNR-BC films (a) and BC, FNR, FNR-BC composite films (b).

### 5.3.6 Biodegradation in Soil

Biodegradation behavior is an important property for biocomposites. The study of biodegradation in soil of BC, SNR, FNR, SNR-BC and FNR-BC films was determined in uncontrolled conditions (with an average temperature of  $\approx 30$  °C). The percentage weight loss and the visual analysis of the biodegraded samples after 6 weeks are shown in Table 5.4 and Figure 5.10, respectively. Cellulose can be decomposed in soil by multiple microorganisms. The weight loss of neat BC film was larger than SNR, FNR film and BC composite films. The degradation of BC was 44.3% after 2 weeks, and it took about 4 weeks for BC to completely decompose in soil. BC structures are mainly composed of crystalline cellulose with a minor amount of amorphous cellulose chains. The amorphous regions were more easily degradable by cellulolytic microorganisms than the crystalline regions [152, 153]. Many previous studies have indicated that multiple microorganisms in the soil could completely degrade BC via enzymatic degradation [130, 154, 155]. The weight loss of the SNR and FNR films was relatively lower than BC and the BC composite films at any degradation time. The degradation of NR in natural environments by microorganisms was rather slow because the specific bacteria that can use rubber as carbon source grows slowly [100, 156]. After 6 weeks, the weight loss of SNR, FNR, SNR-BC and FNR-BC were 58.5%, 33.4%, 68.9-93.7% and 51.6-68.3% respectively. SNR-BC and FNR-BC films modified with 1% DRC of SNRL and FNRL were completely degraded in 6 weeks. BC in the composite films was degraded by soil microorganisms much more rapidly than SNR and FNR, and the decomposition of BC induced void formation in the composite films. Then the films were cracked and broken down into small pieces. The percentage weight loss of the SNR-BC and FNR-BC films decreased with increased NR concentration. The weight loss of SNR-BC films was higher than FNR-BC films, which should be attributed to the larger amount of non-rubber content (protein, lipids and carbohydrates) in SNR. Biodegradability could also relate to the water absorbability of BC composite films. The higher water content in films could promote the growth and activity of soil microorganisms that led to the hydrolysis of cellulose and NR, resulting in the increased degradation [83, 157]. Figure 6.10 presents a visual analysis of the biodegradation of BC, SNR, FNR, SNR-BC and FNR-BC films during a period of 2-6 weeks. The decreasing

degradation of BC composite films with higher SNR and FNR concentration was clearly observed, especially at 6 weeks of biodegradation in soil. Black spots were found in SNR, FNR and composite films after 2 weeks in soil, indicating blooms of soil microorganism activity in NR and SNR-BC films, which was a good indicator of biodegradation [83]. Moreover, after 4 weeks in soil, some parts of the composite films disappeared, and in some conditions, the films were degraded completely. Therefore, SNR-BC and FNR-BC films could be biodegradable in soil.

**Table 5. 4** Weight losses of BC, SNR, FNR, SNR-BC and FNR-BC films in soil

Samples	Weight loss (%)			Samples	Weight loss (%)		
	2 weeks	4 weeks	6 weeks		2 weeks	4 weeks	6 weeks

### 5.3.7 Dielectric properties

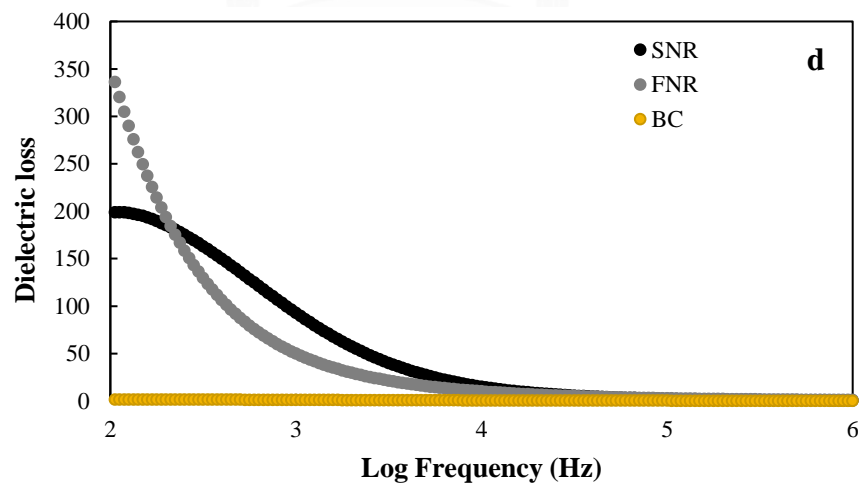

The dielectric properties of materials are an important parameter for designing and predicting the behavior of electronic materials such as capacitors, semiconductor devices, radio propagation, remote sensors and insulating material. The dielectric properties of any polymer depend on its chemical composition, structure cations, dipole moment and space charge polarizations [104]. The dielectric constant is defined as the ability of a material to store energy from an external electrical field, and the dielectric constant of a material depends on the polarizability of the molecules. The polarizability of nonpolar molecules arises from electronic and atomic polarization, whereas the polarizability of polar molecules arises from orientation polarization [128]. The dielectric constant and dielectric loss of BC, SNR, FNR, SNR-BC and FNR-BC films are presented in Figure 5.11. The frequency dependence of the dielectric properties at ambient temperature was observed. In all cases, the dielectric constant and dielectric loss of neat BC, SNR, FNR and BC composites decreased with increasing frequency due to the attribution of relaxation behavior. The dielectric constant of the BC film was very low in the range of 0.48-3.12. The BC chain composed of a H-bond from the hydroxyl group resulted in greater polarity, which lead to polarization in the BC matrix [158]. The dielectric constants of SNR and FNR were in the ranges of 51.92 - 274.20 and 25.15 - 90.74, respectively, at 100 - 1,000 Hz, as shown in Figure 5.11c. The dielectric constants of SNR and FNR were very large when compared to that of CNR (the dielectric constant of CNR is in the range of 1.8–2 [151]), which could be attributed to the different amount of rubber and non-rubber content in SNR, FNR and CNR. The dielectric constants of the SNR-BC and FNR-BC films are shown in Figure 5.11a, b, respectively. The dielectric constant of neat SNR was larger than that of FNR, and the dielectric constant of the SNR-BC films was higher than the FNR-BC films at all filler content. The rubber content (polyisoprene) in SNR and FNR is a nonpolar component, but proteins and phospholipids in NR are polar components [159]. It was suggested that proteins in NR should have a strong effect on the dielectric constant of NRL and NR films. Previous research found that deproteinizing NRL resulted in a significant decrease in the dielectric constant and a dielectric loss of NRL [159, 160]. The protein content in SNRL (18.50 wt%) was higher than FNRL (4.75 wt%); therefore, SNR and SNR-BC

films were more polar than FNR and FNR-BC films. Moreover, the increase of SNR in BC matrices resulted in higher dipoles or orientation polarization; thus, the dielectric constant was enhanced. Previous work by Kosumphan et al. [161] reported the dielectric constant and dielectric loss of SNRL, which were both higher than those of CNRL. In addition, they found that the proportion of pure SNRL in a contaminated serum (cassava and calcium carbonate) decreased, resulting in a decreased dielectric constant. The dielectric constant of SNR-BC and FNR-BC films was found to increase with increasing SNR and FNR concentration. The high amount of SNR and FNR in BC matrices could result in high polar components with a large dielectric constant.

The dielectric loss factor presents the amount of energy loss from a material due to the movement or rotation of the atoms or molecules in an alternating electric field [128]. The frequency dependence of dielectric loss of BC composites is shown in Figure 5.11d-f. The values of dielectric loss exhibited a similar trend as those of the dielectric constant, which increased with increased filler content but declined with increases in frequency. The increase of SNR and FNR proportions in BC matrices enhanced the polar groups in the BC composite films, which led to the enlargement of orientation polarization, resulting in relatively high energy loss. Especially at low frequencies, natural proteins and phospholipids in NR could increase dielectric dissipation due to ionic conductivity, which facilitated the increase in dielectric loss [160].

**Figure 5. 11** Dielectric constant of SNR-BC (a) and FNR-BC (b) and pure SNR and FNR (c) and dielectric loss of pure SNR and FNR (d) and SNR-BC (e) and FNR-BC (f).

### 5.3.8 Electrical conductivity

The electrical conductivity of BC, SNR, FNR, SNR-BC and FNR-BC composites is shown in Figure 5.12. The neat BC film exhibited low electrical conductivity at  $\sim 6.1 \times 10^{-13}$   $1/\Omega \cdot \text{cm}$ . The electrical conductivity of SNR and FNR were  $1.9 \times 10^{-10}$  and  $4.4 \times 10^{-9}$   $1/\Omega \cdot \text{cm}$ , respectively. Therefore, the electrical conductivity of FNR was slightly larger than that of SNR. The electrical conductivities of SNR and FNR were higher when compared to that of CNR (the electrical conductivity of CNR was  $2.1 \times 10^{-15}$   $1/\Omega \cdot \text{cm}$ ), which could be attributed to the different amount of rubber and non-rubber content in SNR, FNR and CNR. Moreover, the electrical conductivity

of SNR-BC films was higher than that of FNR-BC films due to larger amount of SNR content in BC matrices. The electrical conductivities of SNR-BC and FNR-BC films increased with increasing NRL concentration and immersion temperature. The maximum values of electrical conductivity of SNR-BC and FNR-BC at  $1.3 \times 10^{-10}$  and  $2.1 \times 10^{-11}$   $1/\Omega \cdot \text{cm}$ , respectively were obtained at the immersion temperature of  $60^\circ\text{C}$ .

## CHAPTER VI

### CONCLUSIONS AND RECOMMENDATIONS

#### 6.1 Conclusions

**6.1.1** NR composites filled with BRHA, BRHAT and WRHA were successfully prepared via a latex aqueous microdispersion process with the use of sodium alginate as a dispersing agent. SEM images presented good dispersion of RHAs in composite matrices and no phase separation with RHA loading in the range of 20–100 phr. The filler–rubber interactions of composites were observed via FTIR analysis. Types of RHAs and filler loading had strong effect on chemical and mechanical properties of NR-composites. NR-T composites exhibited lower chemical and mechanical properties than NR-B and NR-W due to the loss of some metal ions after acid washing pretreatment. The effective crosslinking of alginate in the composites by  $\text{CaCl}_2$  was achieved on NR–WC films. The mechanical properties of NR composite films were improved by BRHA, BRHAT and WRHA reinforcement. NR–WC at filler loading of 100 phr presented the highest tensile strength and the lowest water and toluene uptake. The tensile strength of NR–WC was almost as large as that of NR-WS at same filler loading (100 phr). The results indicated that crosslinking NR–W composites by  $\text{CaCl}_2$  could promote good filler–alginate–NR interaction, enhanced mechanical properties and structural stability of NR–WC films. The preliminary biodegradation in soil for 3 months revealed relatively improved biodegradability with RHA loading. The weight losses of NR–Bs, NR-Ts and NR–Ws after 3 months in soil were about 7.6–13.0%, 5.3–14.5% and 7.6–18.4%, respectively.

Moreover, the reinforcement considerably improved electrical properties of the composite films. Dielectric constant, dielectric loss factors and electrical conductivity of the composite films were enhanced with RHA loading. Dielectric properties had a trend similar to that of electrical conductivity of NR composites reinforced with RHA. NR-B composites showed higher dielectric properties and electrical conductivity than NR-W and NR-T composites due to the larger amount of metal oxides and carbon residues in BRHA. However, after crosslinking the composites by  $\text{CaCl}_2$  or by sulfur vulcanization, the dielectric constant, dielectric loss

and electrical conductivity of composites significantly dropped due to the decrease in space polarization. Since the NR composites filled with RHAs exhibited improved properties in terms of mechanical properties, chemical resistance, biodegradability and electrical properties, they have potential for further development as stretchable conductive substrate or semiconducting polymer films for electronic applications.

**6.1.2** BC reinforced with SRN and FRN were successfully prepared by immersing BC into diluted SNRL and FNRL suspensions at different immersion temperatures (50-60 °C). It was found that SNR could more rapidly diffuse and be absorbed into BC matrices than FNR. At the higher immersion temperature of 60 °C, a larger amount of SNR and FNR could be integrated into BC matrices compared to that at 50 °C. FTIR analysis indicated no chemical interaction between SNR, FNR and BC. The tensile strength and elongation at break of BC composite films were improved by SNR and FNR reinforcement. The composite film of 5SNR-BC60 exhibited the highest elongation at break at 28 %, whereas the film of 5 FNR-BC50 exhibited the highest tensile strength at 177 MPa. The SNR-BC and FNR-BC films demonstrated good structural stability and high resistance to both water and toluene. From biodegradation tests in soil over 6 weeks, the biodegradability of SNR-BC and FNR-BC was 69-100% and 52-100%, respectively, at the end of 6 weeks in soil, depending on the NR content in the composite films. Moreover, the integration of SNR and FNR into BC demonstrated significantly enhanced dielectric properties of the BC composite films. The composite film of 5SNR-BC60 presented excellent dielectric properties in terms of dielectric constant (170 at 100 Hz) and dielectric loss (76 at 100 Hz). Therefore, the significant improvement of BC composite films in terms of mechanical strength, flexibility, structural stability, chemical resistance and electrical properties was achieved by using cheap natural products from NRL (SNR and FNR) as reinforcement agents. From these improved properties, the composite films display potential for further development as semiconducting polymer films and flexible electronic devices for electronic applications.

## 6.2 Recommendations

6.2.1 The study in Chapter IV demonstrated that the composites of NR-W100 and NR-WC100 exhibited good mechanical properties (excellent elongation at break), good chemical resistance and the films can be biodegraded in soil. The crosslinking NR-W composites by  $\text{CaCl}_2$  under mild condition without toxic chemicals could effectively improve chemical and mechanical properties of the films. For future medical applications, the evaluation of film cytotoxicity should be carried out.

6.2.2 The dielectric properties of NR-RHA composites should be improved. For further developing NR-RHA composites as conductive or semiconductor materials, the NR-RHA composite should be added with some conductive filler, such as carbon black, graphite or metallic powders for reducing dielectric loss and increasing electrical conductivity.

6.2.3 The study in Chapter V demonstrated that BC reinforced with skim/fresh natural rubber latex (5SNR-BC60 and 5FNR-BC50) exhibited good chemical and mechanical properties (excellent tensile strength). The composite films can be biodegraded in soil with no toxic components. For the potential uses in medical applications, the evaluation of film cytotoxicity should be carried out.

6.2.4 Thermal stability and thermal degradation properties are importance for both biomedical material and electrical application. Therefore, in the further study, the NR composites and BC composites should be characterized in thermal stability and thermal degradation properties.
