# # 6170173121 : MAJOR CHEMICAL ENGINEERING

KEYWORD: Photoreduction, TiO<sub>2</sub>, Mechanism, Pathway, Isotope effect

Duangthip Sattayamuk : MECHANISM AND REACTION PATHWAYS OF CO<sub>2</sub> AND HCO<sub>3</sub><sup>-</sup> PHOTOREDUCTION TO HYDROCARBONS. Advisor: Prof. PIYASAN PRASERTHDAM, Ph.D. Co-advisor: SUPAREAK PRASERTHDAM, Ph.D., Prof. Oswaldo Rafael Nunez Sosa, Ph.D.

CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> photocatalytic reductions in water, using P25 Titanium dioxide, produce gas products at the order of the following rate: CO>H<sub>2</sub>>CH<sub>4</sub>, using bicarbonate as a substrate, reduction rates are ca. 5 times faster than using CO<sub>2</sub> due to the adsorption constant of CO<sub>2</sub> on the TiO<sub>2</sub> surface is smaller than the bicarbonate. Langmuir-Hinshelwood kinetic model was used to describe the mechanism; therefore, adsorption constant (K) and the rate of maximum substrate coverage (k) at different charges of P25-surface were readily obtained. The K constant of TiO<sub>2</sub>-adduct formation favors no charge surface but k constant favors positive charge surface. Most of the products formed come from partitioning of the radical anion (TiO<sub>2</sub>-CO<sub>2</sub><sup>-</sup>) in the rate-limiting step. However, the bicarbonate absorption at O<sub>v</sub> promotes alternative pathways. This provides more CO and H<sub>2</sub> production. Solvent isotope effect (H<sub>2</sub>O Vs. D<sub>2</sub>O) is ca. 1.5. This means that during the radical anion formation in the transition state, there is H being transferred from water in the radical anion intermediate step. In addition, the collapse of anatase and rutile phases from sonication increases CH<sub>4</sub> production rate and selectivity due to improved charge separation that reduces alternative pathways.

## ACKNOWLEDGEMENTS

I am grateful to my advisor, Professor Dr. Piyasan Prasertdam, co-advisor, Dr. Supareak Prasertdam, and Prof. Dr. Oswaldo Rafael Nuñez Sosa for significant support, advice for completing this project successfully. Furthermore, I would be grateful to Dr. Chalida Klaysom, as a chairman, Professor Dr. Muenduen Phisalaphong, and Assistant Professor Dr. Okorn Mekasuwandumrong, as the members of the thesis committee and thankful to your correctness and suggestion in this work.

In addition, thanks to all companions and staff of Center of Excellence on Catalysis and Catalytic Reaction Engineering, Department of Chemical Engineering, Faculty of Engineering, Chulalongkorn University, who always give assistance and encouragement throughout this work.

Finally, I gratefully thank my family for their support and encouragement throughout my study and this thesis.

# CHAPTER I

## INTRODUCTION

### 1.1 Introduction

CO<sub>2</sub> photoreduction is one of the photocatalytic processes that have gained much attention. This reaction is the capacity to transform the CO<sub>2</sub> to hydrocarbon. It uses solar energy for reaction activation, it is easily controlled and of low cost with also low pollution emission [1]. For effective use of reactions, understanding the reaction mechanism is important. There are several mechanisms proposed [2] but only a few studies focus on describing the rate limiting step. In general, there are two views of rate limiting step. First is substrate adsorption and product desorption [3]. Second is CO<sub>2</sub> and H<sub>2</sub>O charge transfer of CO<sub>2</sub> reduction and H<sub>2</sub>O oxidation on catalyst [4]. These rate limiting step have been proposed in pseudo-first order kinetic.

CO<sub>2</sub> is expected to be the adsorbed substrate on surface catalyst [5],[6]. However, when CO<sub>2</sub> gas is dissolved in the aqueous phase, bicarbonate ion (HCO<sub>3</sub><sup>-</sup>) is the highest content of carbonate species [7]. Some research results show that hydrocarbon compounds can be produced from using HCO<sub>3</sub><sup>-</sup> as the substrate in photoreduction [8]. Therefore, the mechanism of the HCO<sub>3</sub><sup>-</sup> photoreduction process has not been studied in detail. In this study, mechanism and pathways of CO<sub>2</sub> or HCO<sub>3</sub><sup>-</sup> photoreduction, have been described by using Langmuir-Hinshelwood approach. Therefore, kinetics LH parameters are used to explain the behavior of adsorbed molecules (K) on the catalyst surfaces and the rate at maximum adsorption (k) [9]. These constant values are associated to the rate determining step of the photoreduction. The proposed rate determining step is supported by using solvent isotope effect [10].

For photoreduction, the factors of catalyst type, pH, and others affect the photoreaction [11]. In the aqueous phase, the pH in solution is an important variable,

which influences the electron charge on the catalyst surface. The surface charge species affect the capability of activated reaction [12].

Many semiconductors are used in photocatalysis since an electron in the valence band can be excited to the conduction band by adsorbing photon from light irradiation [13]. Titanium dioxide ( $\text{TiO}_2$ ) is commonly photocatalyst. Titanium dioxide has an energy bandgap potential to cover the redox potential of  $\text{CO}_2$  photoreduction. Also, It is highly stable in reaction, available, and economical [14]. Commercial P-25 shows improved activity by the sonication method, [15] due to a synergy effect of the mixed two phases as compared to lower activity when the two phases are not mixed.

This research studied the mechanism and reaction pathway of  $\text{CO}_2$  and  $\text{HCO}_3^-$  photoreduction to hydrocarbon products with the effect of pH in solution by using the Langmuir-Hinshelwood kinetic model. Solvent ( $\text{H}_2\text{O}$  Vs.  $\text{D}_2\text{O}$ ) kinetic isotope effect has been measured for the reactor headspace gases detected. The pathways of reaction are identified by comparison of various product concentration ratios that are produced at the reaction time. In addition, sonicate pre-treatment method, in order to increase activity and selectivity performance, has been tested.

## 1.2 Objective

To study the mechanism and reaction pathways of  $\text{CO}_2$  and  $\text{HCO}_3^-$  photoreduction to hydrocarbons in solution at different pH by using commercial  $\text{TiO}_2$  (P-25) as photocatalyst. P-25 pre-treatment by sonication performance in rate and selectivity enhancements.

### 1.3 The scope of the research

#### 1.3.1 CO<sub>2</sub> and HCO<sub>3</sub><sup>-</sup> photocatalytic reduction to hydrocarbon products

The activity of the reaction was specified by hydrocarbons production rates from the CO<sub>2</sub> and HCO<sub>3</sub><sup>-</sup> photocatalytic reduction with a cylindrical quartz reactor system that operates at 45°C, ambient pressure with UV-light irradiation for 4 hours.

#### 1.3.2 Mechanism of CO<sub>2</sub> and HCO<sub>3</sub><sup>-</sup> photocatalytic reduction

Langmuir-Hinshelwood kinetic model was used to explain the mechanism of CO<sub>2</sub> and HCO<sub>3</sub><sup>-</sup> photocatalytic reduction. The kinetic model depends on the activity result of a reaction in each condition. The rate limiting step of reaction was confirmed by the solvent isotope effect value.

#### 1.3.3 The Effect by pH of the reaction.

The pH of the solution that affects to surface charge of catalyst was varied by adding buffer NaH<sub>2</sub>PO<sub>4</sub>, 1 M of NaOH, and HCl solution before starting the experiment.

#### 1.3.4 Effect of treatment on the catalyst for photoreduction.

Compare activity and selectivity between the original commercial TiO<sub>2</sub> and pre-treated TiO<sub>2</sub> by sonication method in the HCO<sub>3</sub><sup>-</sup> photocatalytic reduction.

#### 1.3.5 Characterization of the catalyst

The catalysts were characterized by using X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD), UV-VIS Spectroscopy (UV-VIS), Scanning electron Microscope- Energy Dispersive X-ray Spectrometer (SEM- EDX), N<sub>2</sub> temperature-programmed desorption (BET) and Photoluminescence (PL).

## 1.4 Research methodology

## CHAPTER II

### BACKGROUND AND LITERATURE REVIEWS

#### 2.1 Solar energy

The industries in the world have increased that resulting in an increase in demand for energy every year, in which the energy sources are limited and rapidly disappear. While the energy consumed has caused pollution to the environment, such as the main greenhouse gas CO<sub>2</sub> emission, causing global warming to increase from 25 billion tons in 2000 to 35 billion tons in 2017 [16]. Therefore, much research in finding a solution to reduce critical effects and renewable energy is constantly developed. One method is using solar energy, which is unlimited in irradiation energy (50,000 EJ on the earth's surface) and does not emit pollution while using it as an energy source. Solar energy is radiation and the heat from the sun, which has been developed to be combined with technologies for various benefits, such as heating, electrical energy conversion, salt production, and photocatalytic reactions, etc. [17].

Photocatalytic reduction of the greenhouses gas to produce hydrocarbon products is a promising process which can reduce greenhouse gas emission from human activity. Photocatalytic CO<sub>2</sub> reduction is one of the reactions that can reduce the principal gas of global warming.

#### 2.2 Photocatalysts

Generally, photocatalysts are the semiconductor that consists in compounds in between metal and non-metal elements, so this material has electrical conductivity between the conductor and insulator [18]. The semiconductor consists of a valence band (VB) and a conduction band (CB) at different potential energy levels, the gap between the energy level of CB and VB is the energy bandgap (EG). So that, photocatalyst catalyzes reaction by absorbing photons from energy light irradiation to

to produce an excited-state, a transient step of the electron-hole pair process ( $e^-/h^+$ ) [19].

The electron-hole pair process is the excited-electron transfer from VB to CB that makes the conduction band to have an excess electron ( $e^-$ ); therefore, more negative potential to reduce the adsorbed reactant. In contrast, the valence band creates an empty electron state or a hole ( $h^+$ ) to be more positive potential and induce the adsorbed reactant in the system to be oxidized [20].

The redox reaction on photocatalyst with considered species compound in the system depends on the redox potential energy of oxidized species agent ( $E_1$ ) and reduced species agent ( $E_2$ ), the potential energy level of the conduction band (CB) and valence band (VB). When the electron-hole pair process occurs, as shown in Figure 1, the conduction band that has more negative potential than the redox potential energy of oxidized species agent will reduce electron to oxidized species agent ( $\text{Red}_1$  to  $\text{OX}_1$ ) as the reduction reaction. At the same time, the valence band that has more positive potential than the redox potential energy of reduced species agent will oxidize electron to reduced species agent ( $\text{Red}_2$  to  $\text{OX}_2$ ) as the reduction reaction [21].

**Figure 1** Schematic illustration of the photoexcitation process in a semiconductor particle.  $\text{OX}_1$ ,  $\text{Red}_1$ ,  $\text{OX}_2$ , and  $\text{Red}_2$ , represent, respectively, the oxidized and the reduced species of two different redox couples.

Nevertheless, the transient step of the electron-hole pair process can be inhibited and reduce activity when an electron-hole recombination process occurs. The electron-hole recombination is excited- electron from the valence band to conduction band do not has enough activate energy. It will go back to hole in the valence band [22].

### 2.3 Titanium dioxide

Titanium dioxide ( $\text{TiO}_2$ ) is one of the semiconductors widely used in photoreaction for reducing contaminants in water sources [23] and greenhouse gases in the atmosphere [24]. The reaction is not violent and does not produce toxic substances [25].

Molecular weight is  $79.9 \text{ g.mol}^{-1}$ , the boiling point is  $1830 \text{ }^\circ\text{C}$ . Titanium dioxide is an n-type semiconductor compound of a Titanium transition metal bond with Oxygen's around. There is a crystallography phase with different energy bandgaps such as anatase in the tetragonal system (EG = 3.2 eV), rutile in the tetragonal system (EG = 3.0 eV), and brookite in the orthorhombic system (EG = 2.8 eV) as shown in Figure 2. Due to this difference of crystal systems which these different distances between Ti-Ti or Ti-O atoms lead to unequal energy levels [26], [27].

**Figure 2** Representations of the TiO<sub>2</sub> anatase, rutile, and brookite forms.

**Table 1** Crystal structure properties for anatase, rutile and brookite phase of TiO<sub>2</sub>

Property	Anatase	Rutile	Brookite
Crystal bulk structure	Tetragonal	Tetragonal	Orthorhombic
Atoms per unit cell [Z]	4	2	8
Crystal size (nm)	<11	>35	11-35
Lattice parameter (nm)	a = b = 0.3785, c = 0.9514	a = b = 0.4594, c = 0.2959	a = c = 0.5436, b = 0.9166
Space group	D <sub>4h</sub> <sup>19</sup> - I4 <sub>1</sub> /amd	D <sub>4h</sub> <sup>19</sup> - P4 <sub>2</sub> /amd	D <sub>2h</sub> <sup>15</sup> - Pbca
Unit cell volume (nm <sup>3</sup> )	0.1363	0.0624	NA
Density (g.cm <sup>-3</sup> )	3.83	4.24	4.17
Band gap (eV)	3.26	3.05	NA
Hardness (Mohs)	5.5-6	6-6.5	5.5-6

From properties Table 1 [28], the anatase phase of titanium dioxide has an energy band gap at 3.26 eV that can be excited by absorbing photon under UV irradiation wavelength in 384 nm. In comparison, the rutile phase has an energy band gap at 3.05 eV that can be excited by absorbing photon under visible light wavelength at 410 nm. The rutile can be transferred electron easier than the anatase because of the lower energy bandgap [29].

Huilei Zhao., et al. (2013) [30] used pure anatase, rutile and brookite phase of titanium dioxide in CO<sub>2</sub> photoreduction. The production rate of carbon monoxide (CO) is 12 μmol.g<sup>-1</sup>.h<sup>-1</sup> (pure anatase phase), 0.75 μmol.g<sup>-1</sup>.h<sup>-1</sup> (pure brookite phase). Moreover, the best activity was obtained from the mixing phase of the 75% anatase phase with 25% brookite phase.

Wenzhang Fang., et al. (2017) [31] investigated the activity from varying ratio anatase and rutile phase of TiO<sub>2</sub> by reducing the anatase phase in TiO<sub>2</sub> photocatalysts with H<sub>2</sub> thermal treatment. For the production rate of CO<sub>2</sub> photoreduction to CO, the

pure rutile phase had  $0.5 \mu\text{mol.g}^{-1}.\text{h}^{-1}$  while mixing of 26% anatase and 74% rutile phases had  $0.8 \mu\text{mol.g}^{-1}.\text{h}^{-1}$ . The selectivity of methane production was increased as increasing in the anatase phase, but the CO production rate was decreased.

## 2.4 Possible photoreduction mechanism and pathways

Photocatalytic  $\text{CO}_2$  reduction mechanism in the aqueous phase has been studied and anticipated the possible pathway. The photoreduction begins by photocatalyst absorb photon from light irradiation to be excited-state. The catalyst will enter the transient step of generating the electron-hole pair ( $e^-/h^+$ ) and start a redox reaction. The electron ( $e^-$ ) in the valence band is excited to conduction band while the valence band generates the hole ( $h^+$ ).

The hole in the valence band will act as a reducing agent and induce  $\text{H}_2\text{O}$  on catalyst surface to oxidize electron from  $\text{H}_2\text{O}$  with oxidation reaction. The oxidized  $\text{H}_2\text{O}$  will break its bond to be protons ( $\text{H}^+$ ) and hydroxide ion ( $\text{OH}^-$ ). The protons will oxidize the electron in the conduction band to be hydrogen radical ( $\text{H}^\bullet$ ) that is an indispensable hydrogen atom source to produce hydrocarbon products. At the same time, the hydroxide ion will continue to reduce electron to hole in the conduction band and produce hydroxyl radical ( $\text{OH}^\bullet$ ) [32].

For producing hydrocarbon from photocatalytic  $\text{CO}_2$  reduction, the dissolved carbon dioxide in the  $\text{H}_2\text{O}$  aqueous solution is a carbon atom source to produce hydrocarbon products in photoreduction. The carbon dioxide as oxidized species agent adsorbs on the active site of an exciting photocatalyst to be oxidized electron from the conduction band. After that, carbon dioxide form  $\text{CO}_2^\bullet$  radical anion (Eq. 10) and

continuously attract hydrogen radical to form carbon monoxide (CO) as first hydrocarbon product and hydroxide ion (OH<sup>-</sup>) (Eq. 8). Produced carbon monoxide on surface continuously reduces electrons to form  $\dot{\text{C}}\text{O}^-$  radical anion species (Eq. 9) and attract with hydrogen radical to form first carbon radical ( $\dot{\text{C}}$ ) (Eq. 10) that will bind with hydrogen radicals until form hydrocarbon molecule (Eq. 12-13). Methane and methanol are hydrocarbon products of photoreduction that have a different form of  $\dot{\text{C}}\text{H}_3$  with  $\dot{\text{H}}$  radical (Eq. 15) and  $\dot{\text{O}}\text{H}$  radical (Eq. 16) [33].

The two hydroxide ions that produced from  $\dot{\text{C}}\text{O}_2^-$  radical anion and  $\dot{\text{C}}\text{O}^-$  radical anion bind with hydrogen radicals (Eq. 7-9), can be induced and oxidize electron by the hole in valence band with oxidation reaction to form H<sub>2</sub>O [34].

The photoreduction of carbon dioxide can produce various hydrocarbon products. These products Redox potential or thermodynamic potential ( $E_0$ ) in standard conditions at pH = 7, temperature 25°C and pressure 1 atm are shown in Table 2. In order to photoreduction to occur, semiconductor catalyst should have conduction band redox potential more negative than CO<sub>2</sub>  $E_0$  and valence band  $E_0$  more positive than H<sub>2</sub>O  $E_0$  at the reaction pH. Titanium dioxide is one of catalyst that could comply with the  $E_0$  reduction requirement. [35]

**Table 2** Thermodynamic potential ( $E_0$ ) of  $\text{CO}_2$  photoreduction.

Hydrocarbon Product	Chemical Reaction	Thermodynamic potential ( $E_0$ ), NHE at pH 7
	$\text{CO}_{2(\text{g})} + \text{e}^- \rightarrow \cdot\text{CO}_{2(\text{aq})}^-$	-1.99
	$\text{CO}_{2(\text{aq})} + \text{e}^- \rightarrow \cdot\text{CO}_{2(\text{aq})}^-$	-1.90
Formic acid	$\text{CO}_{2(\text{aq})} + 2\text{H}^+_{(\text{aq})} + 2\text{e}^- \rightarrow \text{HCOOH}_{(\text{aq})}$	-0.61
Carbon monoxide	$\text{CO}_{2(\text{aq})} + 2\text{H}^+_{(\text{aq})} + 2\text{e}^- \rightarrow \text{CO}_{(\text{g})} + \text{H}_2\text{O}_{(\text{l})}$	-0.52
Formaldehyde	$\text{CO}_{2(\text{aq})} + 4\text{H}^+_{(\text{aq})} + 4\text{e}^- \rightarrow \text{H}_2\text{C}(\text{OH})_{2(\text{aq})} + \text{H}_2\text{O}_{(\text{l})}$	-0.49
Methanol	$\text{CO}_{2(\text{aq})} + 6\text{H}^+_{(\text{aq})} + 6\text{e}^- \rightarrow \text{CH}_3\text{OH}_{(\text{aq})} + \text{H}_2\text{O}_{(\text{l})}$	-0.38
Methane	$\text{CO}_{2(\text{aq})} + 8\text{H}^+_{(\text{aq})} + 8\text{e}^- \rightarrow \text{CH}_4_{(\text{g})} + \text{H}_2\text{O}_{(\text{l})}$	-0.34

## 2.5 Photocatalytic reduction with Bicarbonate ions

Bicarbonate ion ( $\text{HCO}_3^-$ ) is one of the carbon sources for photocatalytic reduction. It is a form of dissolved carbon dioxide in water and formed at the beginning of the  $\text{CO}_2$  photoreduction pathway. When carbon dioxide dissolves in water by a dissolution process, the carbon dioxide reacts with water to form carbonic acid ( $\text{H}_2\text{CO}_3$ ), hydrogen ions ( $\text{H}^+$ ) and bicarbonate ions ( $\text{HCO}_3^-$ ) as Eq. 16-18 [36].

The bicarbonate ( $\text{HCO}_3^-$ ), carbon monoxide ( $\text{CO}$ ), and methane ( $\text{CH}_4$ ) can be produced by  $\text{CO}_2$  photoreduction as Eq. 22- 28. At the beginning of the  $\text{CO}_2$  photoreduction pathway, the adsorbed carbon dioxide on excited active site is reduced to form a  $\cdot\text{CO}_2^-$  radical anion. After that, the  $\cdot\text{CO}_2^-$  radical anion can attract with

hydroxide ion ( $\dot{\text{O}}\text{H}$ ) to form bicarbonate ( $\text{HCO}_3^-$ ). The bicarbonate can be used as an initial carbon substrate to produce hydrocarbon products [37].

Furthermore, bicarbonate is one of the electron scavengers that can trap electrons and reduce electron from the conduction band to form formate ion ( $\text{HCO}_2^-$ ) as Eq. 26. Formed formate ion is trapped with hydroxide radical ( $\dot{\text{O}}\text{H}$ ) to form hydroxide ion ( $\dot{\text{C}}\text{O}_2^-$ ) (Eq. 27) [38] that can continually bind with another radical to produce hydrocarbon product. This process like  $\text{CO}_2$  photoreduction pathway as Eq. 11-16.

## 2.6 Photocatalytic reduction and pH dependency

The pH of the solution is important variables influencing the photocatalytic reduction process in the aqueous phase. For titanium dioxide surface, pH resulting in charge surface is changed as acid-base equilibrium reaction (Eq. 28-29) [12]. The pH influencing the charged surface of the catalyst has been identified by using the isoelectric point ( $\text{pH}_{\text{IEP}}$ ) or the point of zero charges ( $\text{pH}_{\text{PZC}}$ ), which is pH of no electrical charge on the only external surface or both internal and external surface of catalyst particle [39]. The  $\text{pH}_{\text{PZC}}$  is estimated with averaged  $\text{pK}_a$  of pure positive and negative charge surface condition ( $\text{pK}_{a1} = 4.5$ ,  $\text{pK}_{a2} = 8$ ), The estimated  $\text{pH}_{\text{PZC}}$  of Degussa P25 is 6.2, which the titanium dioxide show no charge or neutral charge surface [12].

Therefore, the titanium dioxide in pH 6.2 aqueous solution is hydrated with  $\text{H}_2\text{O}$  to have a hydroxyl group on the surface ( $\text{Ti-OH}$ ) as a neutral charge surface [40]. Lower  $\text{pH} < 6.2$  or acidic condition contributes to a higher amount of hydrogen ion ( $\text{H}^+$ ) that protonated to an oxygen atom in the hydroxyl group to form ( $\text{Ti-OH}_2^+$ ) as a positive charge surface. High  $\text{pH} > 6.2$  contributes to a higher amount of hydroxide ion ( $\text{OH}^-$ ) that attracts the hydrogen atom in hydroxyl group or deprotonated to form ( $\text{Ti-O}^-$ ) as negative charge surface as shown in Figure 3 [41],[42].

**Figure 3** Simplified scheme of the protonation and deprotonation of hydroxylated  $\text{TiO}_2$  surface [43].

The charge surface species affects the absorption and activity of reactants on the catalyst surface. The reactants are adsorbed better when reactant charge is opposite with the charged surface. Furthermore, the appropriate charge surface species of the catalyst also increases the electron transfer efficiency in the transient state and the selectivity of some products [44]. In the case of  $\text{CO}_2$  photoreduction on  $\text{Fe}_3\text{S}_4$  at pH 4.5-9 solution, the highest production rate of methanol is obtained at pH 6.5 since this condition increases  $\text{CO}_2$  solubility in the solvent [45]. For high-pressure  $\text{CO}_2$  photoreduction to hydrogen, carbon monoxide and formic acid products on Degussa P25 ( $\text{TiO}_2$ ) in basic solution at pH 7.5 to 14, the strong basic solution obtained by

adding scavenger that increases CO<sub>2</sub> solubility (pH 14), yields more productivity and selectivity of hydrogen and formic acid [46]. Low pH condition (pH 1-3) results in more methane production from CO<sub>2</sub> photoreduction with Pd/TiO<sub>2</sub> because solution at pH lower than 6 has more amount of hydrogen ion (H<sup>+</sup>), a hydrogen atom source for methane formation [47].

## 2.7 Langmuir–Hinshelwood mechanism

Langmuir-Hinshelwood mechanism, suggested by Irving Langmuir (1921) and developed by Cyril Hinshelwood (1926) is the process that has two reactant molecules adsorb on near the site of the catalyst surface, and these two adsorbed molecules may interact or recombine with each other [5]. Therefore, this process is suitable for the solid-liquid interface reaction or the heterogeneous catalytic [48]. This mechanism can be extended using Langmuir-Hinshelwood kinetics (LH) that is the common kinetics for explaining the reaction mechanism on the heterogeneous surface of the catalyst. The Langmuir-Hinshelwood kinetic model (LH-kinetics) is shown as follows:

$$r = -\frac{d[C]}{dt} = \frac{kK[C]}{1+K[C]} \quad \text{Eq. 30}$$

Where  $r$  is the rate of reaction that is the function of reactant concentration at any time reaction ( $C$ ), the reaction time ( $t$ ), the limiting reaction rate constant at maximum reactant concentration ( $k$ ) and the absorption coefficient of the reactant on the catalyst ( $K$ ). Eq. 30 is approximated to first-order kinetics, if  $1 > K[C]$  in Eq. 30. The LH kinetics is usually approximated to be the first-order kinetics for sustain  $K[C] \ll 1$  condition and approximated to be the zero-order kinetics for sustain  $K[C] \gg 1$  condition. Furthermore, in the cases of reactant adsorption,  $K[C] \ll 1$  is reactant molecules that have low adsorption, and  $K[C] \gg 1$  is reactant molecules having high adsorption [49].

$$r_0 = \frac{kK[C_0]}{1+K[C_0]} \quad \text{Eq. 31}$$

$$\frac{1}{r_0} = \frac{1}{k} + \frac{1}{kK C_0} \quad \text{Eq. 32}$$

The reaction rate constant ( $k$ ) and the adsorption coefficient ( $K$ ) can be estimated from using Eq. 30 in terms of initial reaction rate ( $r_0$ ) as a function of initial reactant concentration ( $C_0$ ) as Eq. 31 with converting the equation form to a linear equation form as Eq. 32 [9].

I. Poulios et al. [48] In the case of photocatalytic degradation on  $\text{TiO}_2$  (P25) in aqueous solution, this reaction was described by using the modified Langmuir–Hinshelwood model to accommodate reactions occurring at a solid-liquid interface. LH equation Eq. 30 was used in terms of initial rate ( $r_0$ ) and the equilibrium bulk-solute concentration ( $C_{eq}$ ) and modified equation to Eq. 33 for linearity plotted as follows:

$$\frac{C_{eq}}{r_0} = \frac{1}{kK} + \frac{C_{eq}}{k} \quad \text{Eq. 33}$$

From experiments, the concentration of substrate decreased with reaction time, and the initial rate was obtained from each condition. The  $K$  and  $k$  constants can be deduced from the slope and the intersection of the trend line from the  $r_0/C_{eq}$  vs  $C_{eq}$  plot (Figure 4).

**Figure 4** Plot of  $r_0$  vs  $C_{eq}$  at different initial concentrations with  $1 \text{ g l}^{-1}$   $\text{TiO}_2$  P-25. Inset: linear transform of  $C_{eq}/r_0$  vs  $C_{eq}$  according to Eq. 33.

## 2.8 Kinetic solvent isotope effects

The kinetic isotope effect (KIEs) is an effect in which the reaction rate is changed by the isotope substrate replacing. The isotope effect is used to describe reaction kinetics, identifying reaction mechanism by determining its rate limiting steps (RLS), Change of isotope substrate makes the equilibrium of the reaction different. Isotope is the same element atoms which have the same atomic number but the different mass number or the different neutron number. For example, for studying the kinetic isotope effect, H<sub>2</sub>O solvent with the one mass number of hydrogen atoms (<sup>1</sup>H) is changed to D<sub>2</sub>O solvent (Deuterium) with the two mass number of hydrogen atoms (<sup>2</sup>H). Reaction rates are measured using H<sub>2</sub>O and D<sub>2</sub>O under the same reaction condition.

$$\text{KIEs} = k_H/k_D \quad \text{Eq. 34}$$

KIEs is investigated by comparing the ratio of the rate constants that depend on the different reaction rate results. The KIEs of deuterium affection is obtained from comparing the ratio of the rate constants ( $k_H/k_D$ ). The different mass number percentage between the lighter and the heavier mass substrate affects how large the KIEs is. Generally, the KIEs of deuterium can yield  $k_H/k_D$  values of low effect ca. 1 to a high value of ca. 7 depending on the reaction. KIEs value indicates the isotope effect type.

### 2.8.1 Primary kinetic isotope effects

Primary kinetic isotope effects (PKIEs) is the large affection which bond of the substrate (R-H) and its isotope substrate (R-D) is broken in the rate limiting step of a reaction. For example, consider a reaction R-H as substrate reacts with X<sup>-</sup> to produce X-H as shown in Eq. 35 and R-H as substrate is changed to R-D as its isotope or deuterium substrate as Eq. 36

After the hydrogen (R-H) is changed to deuterium (R-D) in the considered reaction, cleavage of R-D substrate bond decreases the overall reaction rate during the rate limiting step and gave the KIEs or  $k_H/k_D > 1$ .

If the KIEs = 1 then the step:  $R-H + X^- \rightarrow [R\cdots H\cdots X]$  is not the RLS.

If the KIEs > 1 then the step:  $[R\cdots H\cdots X] \rightarrow R^- + X-H$  is the RLS.

**Figure 5** Primary kinetic isotope effect from aromatic electrophilic substitution in the nitration of benzene [50].

### 2.8.2 Secondary kinetic isotope effects

Secondary kinetic isotope effects (SKIEs) are the small affection which KIEs is around 1 [51]. The isotope bond is not cleaved during the reaction, but its bond is effected by being near to the actual reaction centre. The difference distances between the isotope and the reaction centre positions. These come in three forms of secondary isotope effect:  $\alpha$ -SKIEs,  $\beta$ -SKIEs, and  $\gamma$ -SKIEs effects. The small effects are caused by the activation energy changing in RLS that effect to hybridization and hyperconjugation on the energy of isotope bond.

For  $\alpha$ -SKIEs, there are two types of  $\alpha$ -SKIEs. The normal  $\alpha$ -SKIEs ( $k_H/k_D \geq 1$ ), the reaction rate is reduced when the hybridization degree of the reaction centre in the transition state is lower than the reaction centre in RLS ( $sp^3$  to  $sp^2$ ,  $sp^2$  to  $sp^1$ ). On

the other hand, the inverse  $\alpha$ -SKIEs ( $k_H/k_D \leq 1$ ) increase the reaction rate when the hybridization degree of the reaction centre in the transition state is higher than RLS ( $sp^2$  to  $sp^3$ ) [52].

**Figure 6** The normal secondary isotope effect of  $\alpha$ -phenylmethyl chloride [53].

**Figure 7** The inverse secondary isotope effect of Wheland intermediate [54].

### 2.8.3 Heavy atom isotope effects

The Heavy atom isotope effects have KIEs around 1. The small isotope effect occurs by slightly different from the mass number between the substrate such as  $^{14}N/^{15}N$ ,  $^{20}Ne/^{21}Ne$  and  $^{35}Cl/^{37}Cl$  etc.

### 2.8.4 Solvent isotopic effect

The solvent effect in the reaction is like the primary isotope effect where the solvent can act as the substrate (reaction has excess substrate). The reaction is effected by exchanging isotope solvent like  $H_2O$  to  $D_2O$ . The heavier mass atom of deuterium may change positions in the molecule to be the new molecule that can react in RLS. The solvent interactions may change the energy in the transition state and result in secondary isotope effects.

Oswaldo Núñez et al. [10] studied the solvent isotope effect of glucose photooxidation with large solvent ( $\text{H}_2\text{O}$  vs  $\text{D}_2\text{O}$ ) on  $\text{Bi}_2\text{WO}_6$  semiconductor. From experiment result, the large solvent isotope effects gave  $k_{\text{H}_2\text{O}}/k_{\text{D}_2\text{O}} = 7.8$  and  $6.8$ . These values come from the equilibrium dissociation of  $\text{L}_2\text{O}$  ionization to  $\text{L}^+$  and  $\text{OL}^-$ , ( $\text{L}_2\text{O}$ ,  $\text{L} = \text{H}$  or  $\text{D}$ ). The reaction rate is faster when  $\text{L}^+$  concentration ( $[\text{L}^+]$ ) increase in acidic condition. Therefore, the rate limiting step is the one  $\text{e}^-$  reduction of  $\text{H}^+$  at  $\text{Bi}_2\text{WO}_6$  conduction band. At the conduction band of catalyst (CB), the reduction of  $\text{O}_2$  to  $\text{O}_2^-$  and  $\text{H}^+$  to  $\text{H}_2$  by using  $\text{Bi}_2\text{WO}_6$  as cathode gave the small solvent isotope effect of KIEs 2.4 and 1.9, respectively.

## 2.9 Literature reviews

T. Inoue et al., [55] studied the carbon dioxide photocatalytic reduction in aqueous suspensions of some semiconductor powers ( $\text{TiO}_2$ ,  $\text{ZnO}$ ,  $\text{CdS}$ ,  $\text{GaP}$ ,  $\text{SiC}$ , and  $\text{WO}_3$ ). This reaction could reduce  $\text{CO}_2$  to produce hydrocarbons such as methanol, formaldehyde, formic acid in the aqueous sample, and methane in the gaseous sample. The best semiconductor catalyst for this report was  $\text{SiC}$ , which had conduction band potential near  $\text{CO}_2$  photoreduction to hydrocarbon potential.

Yasar N. Kavil et al., [56] used  $\text{Cu-C/TiO}_2$  as photocatalyst in the  $\text{CO}_2$  photocatalytic system. The catalyst was suspended with a controlled pH solution and stirred in the Pyrex glass reactor that was connected with the  $\text{CO}_2$  cylinder. Before started reaction, the solution with catalyst was purged with super high purity  $\text{CO}_2$  for 30 minutes until saturated in solution and turn off  $\text{CO}_2$  cylinder to stop purging. The reactor must be completely closed to avoid the outer contact. The UV-lamp was turned on and syringe was used to take samples. The maximum of methanol yield was  $2593 \mu\text{mol}_{\text{cat}}^{-1}$  after 5 hours.

K. Koci et al., [57] studied wavelength effect to  $\text{CO}_2$  photoreduction on  $\text{Ag/TiO}_2$  under irradiation by different lamps in the wavelength range 254-400 nm. The main

products, methane and methanol were obtained in higher yields with UV light (254 nm).

K. Wooyul et al., [58] found that pH affects CO<sub>2</sub> photoreduction. Photoreduction activity increases at low pH, to yield the highest methane production due to the excess of protons around the active site that could be used for CO<sub>2</sub> reduction. At high pH ca. 11, CO<sub>2</sub> solubility increases to form an intermediate of carbonate that could produce solar fuel, but it not significant CO<sub>2</sub> reduction probably due to the lack of protons in solution.

Tai-Sing Wu et al., [59] found that Ultraviolet light irradiation on CeO<sub>2</sub> catalysts could increase the photocatalytic activity of the catalyst and reduce electron-hole recombination. The carbon monoxide conversion was increased as the increase of active site Ce<sup>3+</sup> on the catalyst surface and oxygen vacancy by UV-light irradiation time (254 nm, UV-C). Therefore, the increased activity is presented as experimental evidence to confirmed that UV-light irradiation-induced reduction Ce<sup>4+</sup> ions to Ce<sup>3+</sup> ions and created oxygen vacancies.

Terihisa Ohno et al., [60] has shown using TEM photographs and electron diffraction patterns, Degussa P25 (TiO<sub>2</sub> powder) consists of 75% anatase and 25% rutile phase that were separated. When P25 reacted in photoreaction, the anatase and rutile were not reacted together, yielded low activity. Nevertheless, anatase and rutile phase could co-work by using previous HF treatment, which dispersed both phases of the TiO<sub>2</sub> powders in water or 10% HF solution and sonicated for 30 min. After treatment, the coupling of both phases in TiO<sub>2</sub> provides the higher activity of naphthalene photooxidation.

## CHAPTER III

### EXPERIMENTAL

This chapter describes the details of materials and chemicals, reaction measurement, preparation, analysis result equipment, and characterization.

#### 3.1 Materials and Chemicals

**Table 3** List of materials and chemicals, reactant solution, catalyst, calibration standard, and equipment gas supply.

Chemical Name	Formula	Purity (%)	Suppliers
Degussa (P25)	TiO <sub>2</sub>	-	Aeoxide
Sodium hydrogen carbonate	NaHCO <sub>3</sub>	99.0 %	Fluka Chemika
Sodium phosphate	NaH <sub>2</sub> PO <sub>4</sub>	99.0 %	ACROS ORGANICS
Sodium hydroxide	NaOH	99.0 %	EMSURE
Hydrochloric acid fuming	HCl	37 %	EMSURE
Phenol crystallized	C <sub>6</sub> H <sub>5</sub> OH	99.0 %	Panreac
Deuterium oxide	D <sub>2</sub> O	99.9 %	Cambridge Isotope Laboratories, Inc.
Dimethyl sulfoxide, DMSO	C <sub>2</sub> H <sub>6</sub> OS	99.5 %	Sigma-Aldrich
Carbon dioxide	CO <sub>2</sub>	99.99 %	Linde
Methane	CH <sub>4</sub>	99.99 %	Linde
Carbon monoxide	CO	99.99 %	BOC GASES
Hydrogen	H <sub>2</sub>	99.99%	Linde
Helium	He	>99.99%	Linde
Argon	Ar	>99.99%	Linde
Nitrogen	N <sub>2</sub>	>99.99%	Linde
Air Zero	O <sub>2</sub>	>99.99%	BIG (Bangkok Industrial Gas)

### 3.2 Photocatalytic CO<sub>2</sub> reduction measurement

The photocatalytic CO<sub>2</sub> reduction was operated in the slurry batch system, as shown in Figure 8. A sand sparger is installed in the 250 ml three-way cylindrical quartz reactor for bubbling gas to the solution. Catalyst 0.3 g was suspended into a stirred batch reactor, which contained 100 ml of DI water that control pH at 4-7 by used NaH<sub>2</sub>PO<sub>4</sub>, HCl 1M, and NaOH 1M as a buffer, the reactor is sealed with a rubber septum and bubbled CO<sub>2</sub> gas by flowing gas pass sand sparger for 30 minutes. After CO<sub>2</sub> saturated in DI water, the solution in the reactor was measured pH and added some buffer to control pH at the intended condition. The photocatalytic reaction started after turning on UV-light (Philips' Germicidal Ozone UV Quartz Glass UVC Bulb: 16 watts, 6 bulbs), and irradiation continued for 4 hours. The resultant gas samples were taken every 0.5 hours by using 2.5 ml gas-syringe and analyzed by using GC-FID and GC-TCD, Liquid sample was taken only 1 sample at the end time of reaction for analysis with NMR.

**Figure 8** Schematic representation of the photocatalytic CO<sub>2</sub> reaction system.

### 3.3 Photocatalytic $\text{HCO}_3^-$ reduction measurement

The  $\text{HCO}_3^-$  photocatalytic reduction was operated in the slurry batch system, as shown in Figure 9. The cylindrical quartz reactor with 250 ml of total volume. UV-light bulbs (Philips' Germicidal Ozone UV Quartz Glass UVC Bulb: 16 watts, 6 bulbs) were installed around a cylindrical quartz reactor. Catalyst 0.3 g was suspended into a stirred batch reactor by magnetic stirred, which contained 100- 600 mg dissolved  $\text{NaHCO}_3$  in 100 ml of DI water that control pH at 4-7 by used  $\text{NaH}_2\text{PO}_4$ ,  $\text{HCl}$  1M, and  $\text{NaOH}$  1M as a buffer. Then high purity of Argon gases was purged into the reactor for 5 minutes by flowing gas pass the long needle to eliminate air out from reactor at ambient pressure. After that, the reactor was closed during the reaction with a rubber septum. The photocatalytic reaction was started by turning on UV-light, and irradiation was continued for 4 hours. The resultant gas samples were taken every 0.5 hours by using 2.5 ml gas-syringe and analyzed by using GC-FID and GC-TCD, Liquid sample was taken only 1 sample at the end time of reaction for analysis with NMR.

**Figure 9** Schematic representation of the photocatalytic  $\text{HCO}_3^-$  reaction system.

### 3.4 Langmuir–Hinshelwood mechanism

Langmuir-Hinshelwood (LH) kinetic rate ( $r$ ) expression is shown in Eq. 37.

$$r = -\frac{d[C]}{dt} = \frac{kK[C]}{1+K[C]} \quad \text{Eq. 37}$$

If  $\text{CO}_2$  or  $\text{HCO}_3^-$  as substrate at initial of process, LH model is expressed as shown in Eq.38 and 39

$$\text{CO}_2 \text{ photoreduction: } r_i = -\frac{d[\text{CO}_2]_i}{dt} = \frac{kK[\text{CO}_2]_i}{1+K[\text{CO}_2]_i} \quad \text{Eq. 38}$$

$$\text{HCO}_3^- \text{ photoreduction: } r_i = -\frac{d[\text{HCO}_3^-]_i}{dt} = \frac{kK[\text{HCO}_3^-]_i}{1+K[\text{HCO}_3^-]_i} \quad \text{Eq. 39}$$

Where  $r_i$  represent the initial rate of reaction  
 $[ ]_i$  represent the initial concentration of substrate  
 $k$  represents the rate constant at maximum adsorption.  
 $K$  represents adsorption on catalyst constant

$$\text{And } k_{obs} = kK \quad \text{Eq. 40}$$

The initial rate of reaction ( $r_i$ ) in each condition of the experiment can be achieved from the linearity relation of produced hydrocarbon concentration with the reaction time. The constant values ( $k$ ,  $K$ ) can be obtained from the relation of the initial rate of reaction by calculating the slope on the graph before.

### 3.5 $\text{H}_2\text{O}/\text{D}_2\text{O}$ Isotope effect of photocatalytic $\text{HCO}_3^-$ reduction on P25 as photocatalyst

The  $\text{H}_2\text{O}/\text{D}_2\text{O}$  Isotope effect in photocatalytic  $\text{HCO}_3^-$  reduction was operated in the same batch system, as shown in Figure 9. The cylindrical quartz reactor with 250 ml of total volume. 0.03 g of P25 as photocatalyst were suspended into a stirred batch reactor containing 60 mg of dissolved  $\text{NaHCO}_3$  in 10 ml of DI water. pH at 7 was maintained using  $\text{NaH}_2\text{PO}_4$ , HCl 1M and NaOH 1M as a buffer. Then high purity of Argon gas was bubbled into the reactor for 5 minutes to purge air at ambient pressure. After that, the reactor was closed with septum during the reaction. The photocatalytic

reaction was started by turning on UV-light, and irradiation was continued for 3 hours. The resultant gas samples were taken every 0.5 hours by using 2.5 ml gas-syringe and analyzed by using GC-FID and GC-TCD.

### 3.6 Sonicated P25 photocatalyst preparation

Sonicated P25 was prepared by dispersing 10 g of Degussa P25 powder (TiO<sub>2</sub> consist of 75% anatase and 25% rutile phases) in 150 ml water. Sonicated for 30 minutes, centrifuged to separate the water and dried in the oven at 110 °C overnight.

### 3.7 Reaction analysis equipment

#### 3.6.1 Gas-Chromatography

**Table 4** Condition of Gas-Chromatography

Gas chromatography	Shimadzu GC-14A	Shimadzu GC-8A
Detector	FID	TCD
Packed column	Shincarbon ST	Molecular sieve 5A
Carrier gas	He (HP grade, 99.99 vol.%)	Argon (HP grade, 99.99 vol.%)
Make-up gas	Air (UHP grade, 100 vol.%)	-
Column temperature	70 °C	70 °C
Injector temperature	150 °C	150 °C
Detector temperature	150 °C	150 °C
Time analysis	10 minutes	18 minutes
Analyzed product	CH <sub>4</sub>	H <sub>2</sub> , CO

### Conversion and Selectivity calculation

Conversion of this photocatalytic reduction is determined by using the concentration of product at the end time of reaction, initial concentration of substrate as the following equation.

$$\text{Conversion (\%)} = [\text{HCP}]_{t(\text{end})} \times 100\% / [\text{C}]_0 \quad \text{Eq. 41}$$

Where  $[\text{HCP}]_{t(\text{end})}$  is Hydrocarbon concentration at the end time of reaction.

$[\text{C}]_0$  is the initial concentration of the substrate.

The selectivity of this photocatalytic reduction is considered from the concerned product concentration.

$$\text{Selectivity (\%)} = [\text{P}]_{t,i} \times 100\% / [\text{HCP}]_t \quad \text{Eq. 42}$$

Where  $[\text{HCP}]_t$  is Hydrocarbon concentration at the time of reaction.

$[\text{P}]_{t,i}$  is the Concentration of concern product at the time of reaction.

#### 3.6.2 Nuclear magnetic resonance spectrometer (NMR)

Nuclear magnetic resonance spectrometer (NMR) was used for analyzing organic compounds produced at the reactor liquid phase by measuring the FID signal that generated the nuclear emission energy. This energy occurs from the excited element nucleus by using radiofrequency waves.

For produced product in liquid phase such as Methanol ( $\text{CH}_3\text{OH}$ ), Formic acid ( $\text{HCOOH}$ ) in a large amount of water is analyzed by using Fourier Transform Nuclear Magnetic Resonance Spectrometer 500 MHz (NMR 500 MHz) that perform by BRUKER AVANCE III HD/OXFORD 500 MHz with Solvent peak suppression program.

The NMR sample is prepared by using 400  $\mu\text{L}$  of the liquid sample from reaction with 200  $\mu\text{L}$  internal standard that content with 0.012  $\mu\text{mol/mL}$  of phenol and 0.125  $\mu\text{L/mL}$  of DMSO (Dimethyl sulfoxide) in  $\text{D}_2\text{O}$  (Deuterium oxide).

The product compound and phenol peak position were specified by comparing with the DMSO peak position, then compare the product peak area with phenol peak area to calculate the concentration of product in the NMR sample.

The calculation of liquid product in the sample as follows:

Phenol: Phenol has 5 atoms of aromatic Hydrogen in the molecule

Phenol area integration from NMR = (Phenol NMR area)

Phenol concentration in NMR sample = [Phenol] or  $[C_6H_5OH]$

Methanol: Methanol has 3 atoms of Hydrogen bind carbon in the molecule

Methanol area integration from NMR = (Methanol NMR area)

Methanol concentration in NMR sample = [Methanol] or  $[CH_3OH]$

Therefore, Methanol concentration in the NMR sample is

$$[\text{Methanol}] = \frac{[\text{Phenol}] \times \frac{3}{5} \times (\text{Methanol NMR area})}{(\text{Phenol NMR area})} \quad \text{Eq. 43}$$

### 3.8 Characterization equipment

#### 3.8.1 X-ray diffraction (XRD)

The phase crystal structure of the compound was analyzed by the X-ray diffraction technique (XRD) that used X-ray diffractometer (Bruker D8 Advance) with Cu anode,  $K\alpha$ 1-1,544 Å irradiation at various angles between 20 deg and 80 deg with a resolution of  $0.05^\circ s^{-1}$ . Specify the phase crystal structure type by comparison and confirmation from JCODS database: JCPDS card no.21-1272 (anatase  $TiO_2$ ), JCPDS card no.21-1276 (rutile  $TiO_2$ ). The Debye-Scherrer equation calculated the crystallite size.

#### 3.8.2 X-ray photoelectron spectroscopy (XPS)

The binding energy and surface composition (oxidation state) were investigated by X-ray photoelectron spectroscopy (XPS). XPS used an AMICUS photoelectron spectrometer with Mg  $K\alpha$  X-ray source is controlled by KRATOS VISION2 software at a current of 20 mA and 10 KeV. Furthermore, the intensity of Ti 2p and O 1s were intense at binding energy 455-470 eV and 525-540 eV respectively after that the oxidation state species of each element were indicated from NIST XPS database.

### 3.8.3 UV-VIS Spectroscopy (UV-VIS)

The UV-visible absorption spectra of catalyst molecules were detected by Spectroscopy using LAMDA 650 UV/Vis spectrophotometer with wavelength varying between 100-900 nm in the ultraviolet and visible light wavelength (UV-C wavelength is 100-280 nm and 380-740 nm). The light absorption data were obtained by UV Win Lab software from PerkinElmer. UV-VIS result shows diffuse reflectance spectra of catalysts, and the energy band gap can be calculated from its optical absorption edge with Tauc's equation Eq. 34.

$$\alpha h\nu = A(h\nu - E_g)^m \quad \text{Eq. 43}$$

where A is the optical constant, h is Planck's constant,  $\alpha$  is the absorption coefficient,  $\nu$  is  $c/\lambda$  that c is the speed of light in vacuum and  $\lambda$  is the wavelength,  $E_g$  is the optical band gap, and m value is 0.5 for direct transitions and 2 for indirect transitions.

### 3.8.4 Photoluminescence spectroscopy (PL)

The charge separation and the charge-carrier lifetime of catalyst were investigated by Horiba 4P- Fluoromax spectrofluorometer. Photoluminescence spectroscopy used Xenon lamp as the excitation source. Excitation was investigated under wavelength 200-800 nm. The light beam was used to excite the electron in molecule become to an excited state (minority carrier) after that, the excited electron goes down to the equilibrium state. The process of minority carrier recombination a small period of time is known as charge-carrier lifetime.

### 3.8.5 N<sub>2</sub>-Physisorption

N<sub>2</sub> adsorption-desorption experiments were performed to the catalysts at -196 °C by under vacuum 12 hours the multipoint Brunauer-Emmett-Teller (BET) method on a Micromeritics ASAP 2020 instrument. Before the measurement, each sample was degassed under vacuum at 150 °C for 8 h.

## CHAPTER IV

### RESULTS AND DISCUSSION

In this chapter, the physiochemical properties and the catalytic performance of the catalyst were discussed. In this work, the photocatalysts are the pure commercial titanium dioxide (P25) and the sonicated titanium dioxide (Sonic.P25). Both P25 and Sonic.P25 catalysts were characterized by using several techniques as XRD, XPS, N<sub>2</sub> physisorption, UV-vis, PL and SEM. The photocatalytic performance for the conversion and selectivity of CO<sub>2</sub> and HCO<sub>3</sub><sup>-</sup> photoreduction to hydrocarbon products, changing P25 morphology, alternative CO pathway formation and H<sub>2</sub>O/D<sub>2</sub>O solvent isotope effect is reported.

#### 4.1 Characterization

##### 4.1.1 Powder X-ray diffraction (XRD)

The X-ray diffraction pattern of commercial TiO<sub>2</sub> (P25) and Pre-treatment TiO<sub>2</sub> (Sonic.P25) catalyst were shown in Figure 10. Both catalysts consist of two mixture phases, containing the anatase phase and the rutile phase with the same characteristic peaks. The anatase phase of catalysts has 2 $\theta$  and Miller indices is 25.3° (101) main peak, 37.0° (103), 37.8° (004), 38.5° (004), 48° (200), 54.3° (105), 55.1° (211), 62.8° (213), 70.3° (220) and 75.1° (215). The rutile phase is 27.4° (110) main peak, 36.1° (101), 41.3° (111), 53.9° (221), 56.6° (220) and 69.0° (301) [61-63]. The phase composition of catalyst is calculated from the integrated intensities of anatase and rutile phases. The weight fraction of anatase and rutile phases which consist of 80% anatase and 20% rutile phases in both catalysts.

The average crystallite size of anatase and rutile phases was calculated from the main anatase and rutile peak (2 $\theta$  = 25.3° and 36.1°) using the Debye-Scherrer equation [64]. The crystallite size of anatase and rutile phases in P25 is 18.68 nm and

29.24 nm. The Sonic.P25 crystallite size of anatase and rutile phases are slightly smaller than P25 with 18.33 nm and 28.29 nm, respectively. In consequence, the ultrasonic vibration of sonicate pre-treatment can slightly reduce the size of the crystal and does not change the crystal phase structure of the catalyst.

**Figure 10** XRD pattern of P25 and Sonic.P25 catalyst.

#### 4.1.2 X-ray photoelectron spectrometer (XPS)

The XPS binding energy of element composite in the catalyst is shown in Figure. 11-12. The O<sub>1s</sub> peak of O<sub>L</sub> at 529.8 eV is oxygen lattice of oxygen bonding with Ti<sup>4+</sup> in Ti-O-Ti. O<sub>V</sub> at 531.5 eV is Oxygen vacancy or non-oxygen lattice that is OH group with oxygen binding site on the catalyst surface and O<sub>S</sub> at 533.4 eV may be chemisorbed oxygen specie on the catalyst surface that is oxygen attached to another impurity element [65-67]. The binding energy of Titanium (Ti2p), Ti(2p<sub>2</sub>) at 458.6 eV is Ti<sup>4+</sup> and Ti(2p<sub>1</sub>) at 456.8 eV is Ti<sup>3+</sup> in TiO<sub>2</sub>. The Ti<sup>3+</sup> indicates oxygen vacancies. The Ti<sup>3+</sup> was generated to maintain electrostatic balance according to Ti<sup>4+</sup> and O<sup>2-</sup> to the vacant position of oxygens in TiO<sub>2</sub> [68]. Including to the peak area, Ti<sup>3+</sup>/Ti<sup>4+</sup> and O<sub>V</sub>/O<sub>L</sub> area ratios are 0.017 and 0.43 for P25 and 0.022 and 0.79 for Sonicated P25, respectively.

From Table 5, the sonicated P25 has more oxygen vacancy on its surface that could promote more photoactivity of catalyst.

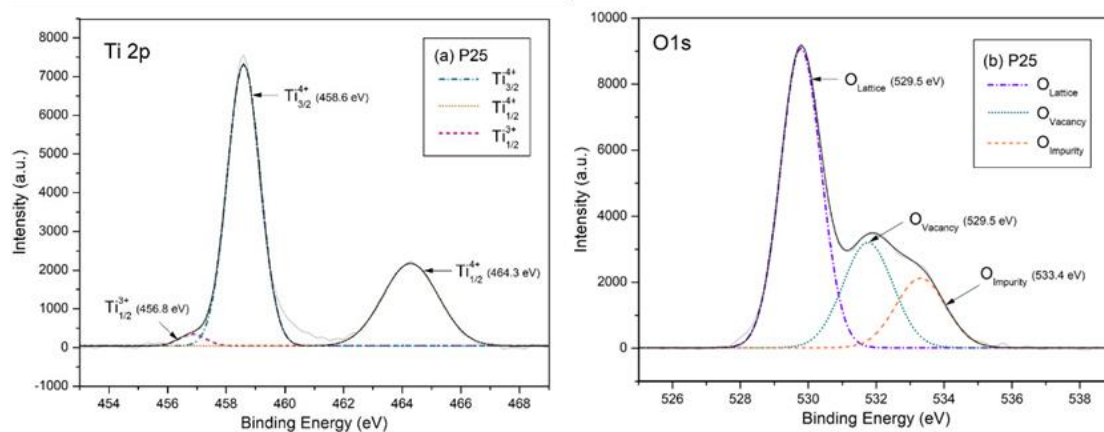

Figure 11 XPS spectra of (a).Ti 2p and (b). O1s of P25 catalyst

Figure 12 XPS spectra of (a).Ti 2p and (b). O1s of Sonic.P25 catalyst

Table 5 The ratios of  $Ti^{3+}$  to  $Ti^{4+}$  and  $O_V$  to  $O_L$  of catalysts.

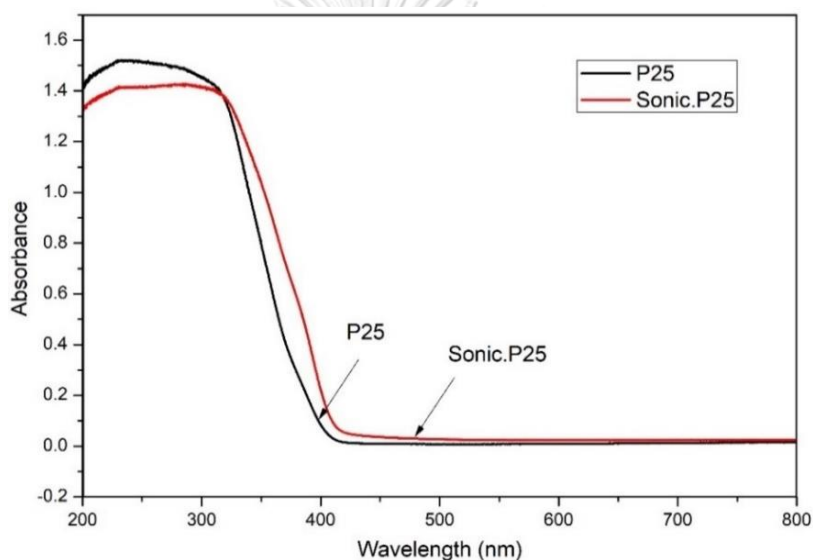

Catalyst	Ratio Ti2p ( $Ti^{3+}/Ti^{4+}$ )	Ratio O1s ( $O_V/O_L$ )
P25	0.017	0.432
Sonic.P25	0.022	0.787

#### 4.1.3 Surface Area Measurement

The surface area of P25 and Sonic.P25 catalyst are specified by using the single-point  $N_2$  physisorption analysis. The P25 and Sonic.P25 have a surface area of  $51.34 \text{ m}^2/g_{\text{cat}}$  and  $51.48 \text{ m}^2/g_{\text{cat}}$ , respectively. Therefore, the sonication was not effect to surface changing in  $TiO_2$  catalyst.

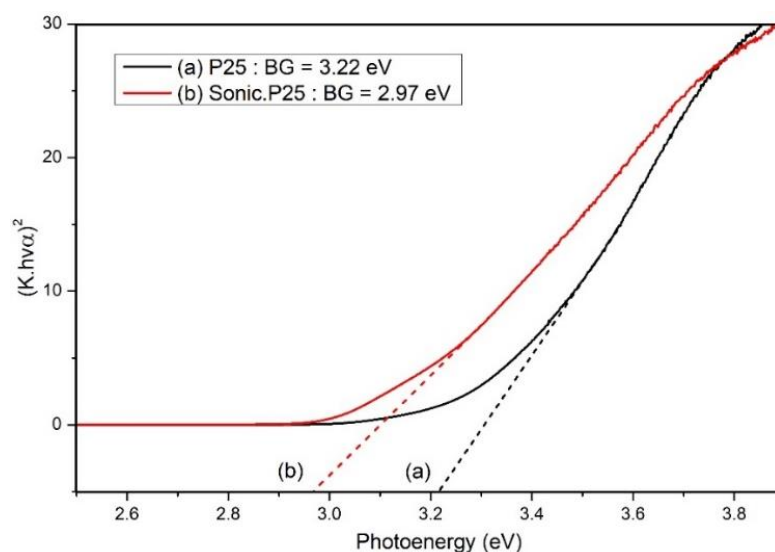

#### 4.1.4 UV-vis absorption spectra

The UV-vis absorption spectra are used to investigate the light absorption of P25 and Sonic.P25, as shown in Figure 13. The sharp absorption band at wavelengths less than 400 nm were associated with the band structure of the catalysts, which is the light region that can excite an electron to transfers from the valence band to the conduction band. The absorption edge of P25 was located at 373 nm, which the catalyst adsorbs the UV-light only while the Sonic.P25 can slightly adsorb the visible light (wavelength > 400 nm) because the absorption edge was located at 404 nm.

**Figure 13** UV-vis absorbance spectra of P25 and Sonic.P25.

From the light absorbance of catalyst at each wavelength, as shown in Figure 13, the energy band gap of P25 and Sonic.P25 catalyst were inferred by using the Tauc's relation (Eq.43) as shown in Figure 14. The plot of  $(\alpha h\nu)^2$  versus the photoenergy ( $h\nu$ ) of each catalyst shown the curve line, which intercepted on the photoenergy as its bandgap energy [69]. The P25 had the wider energy bandgap about 3.22 eV, compared to the Sonic.P25 that had the energy bandgap about 2.97 eV. The narrower energy bandgap of Sonic.P25 resulted in the electrons transferred from the valence band to the conduction band more efficiently [70, 71].

**Figure 14** Tauc's relation for energy band gap determination of P25 and Sonic.P25

#### 4.1.5 Photoluminescence (PL)

The photoluminescence (PL) is a technique for measuring the efficiency and electrical properties of semiconductors such as charge carrier trapping, carrier lifetime and recombination [72]. The results from the light radiation or photon energy emission from the catalyst sample after absorbed the laser-light energy, as shown in Figure 15. Generally, the semiconductor has an electrical property called the energy bandgap, which is the gap of energy level between the conduction band and valence band. When the electrons in the valence band adsorb the light energy more than the energy band gap, then the electrons are excited to the conduction band. But if the adsorbed light energy is not stable or not enough, the excited electrons will go back to the valence band and emit the photon energy [73]. The photo energy emission of electrons in going back to the valence band is the recombination of  $e^-/h^+$  pair. The PL emission spectra of catalysts is shown in Figure 15. The intensity indicates the emission energy of  $e^-/h^+$  recombination rate. P25 had intensity of emission energy more than Sonic.P25. Therefore, the sonicated treatment contributes more charge separation and reduces the recombination rate in the catalyst.

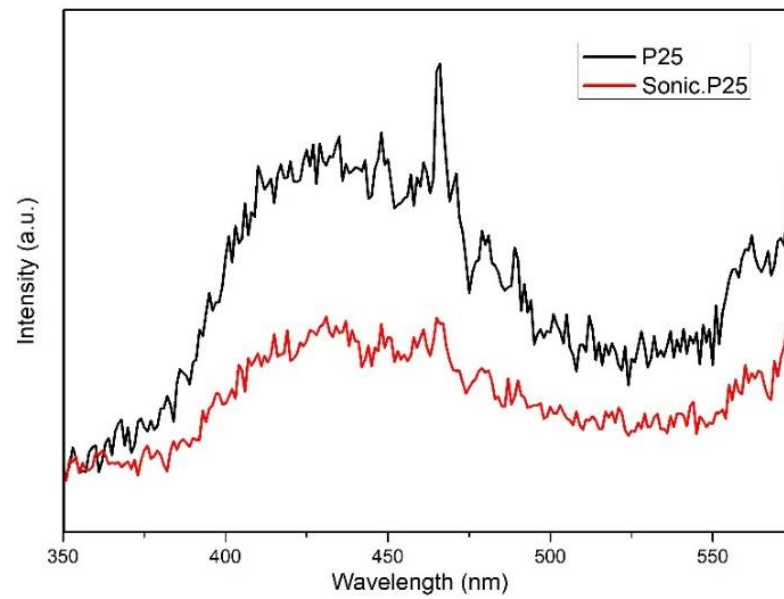

Figure 15 The PL emission spectra of P25 and Sonic.P25

#### 4.1.5 Scanning electron microscopy (SEM)

The morphology of P25 and Sonic.P25 particle, are presented in Figure 16; these micrographs can not be explained by the anatase and rutile phase mixing. The spherical nanoparticles of P25 and Sonic.P25 is not much different from the sonication.

**Figure 16** SEM images of (a-c) P25 and (d-f) Sonic.P25 catalyst

## 4.2 CO<sub>2</sub> Photoreduction experiments

From CO<sub>2</sub> photoreduction experiment, the P25 catalyst was used under the initial concentration of CO<sub>2</sub> in water is  $[\text{CO}_2]_{w0} = 34 \times 10^3 \text{ nmol/ml}_{\text{H}_2\text{O}}$  at pH = 5.41, 5.12 and 4.52, Temperature 45 °C. The detected products in the headspace of the reactor are CH<sub>4</sub>, CO and H<sub>2</sub>. As shown in Figure 17(a), the initial production rate of CH<sub>4</sub> is 1.4-1.6 nmol/ml<sub>H<sub>2</sub>O</sub>·g<sub>cat</sub>·h, 3.2-3.9 nmol/ml<sub>H<sub>2</sub>O</sub>·g<sub>cat</sub>·h for CO, 8.3-11.8 nmol/ml<sub>H<sub>2</sub>O</sub>·g<sub>cat</sub>·h for H<sub>2</sub>. The selectivity is 9%, 20%, 71% for CH<sub>4</sub>, CO and H<sub>2</sub>, respectively. Selectivity slightly changes when changed to other pH values, as well as the production rate of CO and H<sub>2</sub> obtained from the plot of product concentration versus time in Figure 17 (c-d). Furthermore, in the aqueous phase was found a minimal amount of methanol compared to other products, CH<sub>3</sub>OH initial production rate = 0.10 nmol/ml<sub>H<sub>2</sub>O</sub>·g<sub>cat</sub>·h at pH 4.52 measured by HNMR. From Table 6, conversion of each product is very low (%conversion of approximately  $6.3 \times 10^3\%$ ,  $14.1 \times 10^3 \%$  and  $36.6 \times 10^3 \%$  for CH<sub>4</sub>, H<sub>2</sub>, and CO production).

**Table 6** CH<sub>4</sub>, H<sub>2</sub> and CO conversion and selectivity from CO<sub>2</sub> photoreduction in the aqueous phase under P25 catalyst performance at pH = 5.42, 5.12 and 5.42, Temperature 45 °C.

pH	% Conversion $\times 10^3$ (*a)			% Selectivity (*b)		
	CH <sub>4</sub>	H <sub>2</sub>	CO	CH <sub>4</sub>	H <sub>2</sub>	CO
5.4	6.3	14.1	36.6	9.7	22.7	67.6
5.1	6.7	15.0	39.4	10.8	23.8	65.5
4.5	7.0	17.0	51.9	8.8	20.4	70.8

\*a. Calculated using: %Conversion =  $r_i/[\text{CO}_2]_{w0}$ ,

where  $[\text{CO}_2]_{w0} = 1 \text{ atm}/29.41 \text{ atm/M} = 34 \text{ } \mu\text{mole/ml} = 34 \times 10^3 \text{ nmole/ml}$ .

\*b Calculated from products detected at the headspace in reactor : CH<sub>4</sub>, CO and H<sub>2</sub>.

**Figure 17** CO<sub>2</sub> photoreduction result under P25 catalyst performance (a). Rates of CH<sub>4</sub>, H<sub>2</sub> and CO production at pH = 5.42, 5.12 and 5.42. (b-d). Initial rates of CH<sub>4</sub>, H<sub>2</sub> and CO production at pHs studied.

The CH<sub>4</sub> formation pathways of CO<sub>2</sub> photocatalytic on TiO<sub>2</sub> with H<sub>2</sub>O have been proposed [73]. These pathways involved homolytic bond cleavage and formation (Eq. 46-48). Firstly, the adsorbed CO<sub>2</sub> is reduced to form the radical anion  $\dot{\text{C}}\text{O}_2^-$  at the conduction band (Eq. 44), while water is oxidized at the valence band to form  $\dot{\text{O}}\text{H}$  and  $\dot{\text{H}}$  radicals (Eq. 45). The radical anion  $\dot{\text{C}}\text{O}_2^-$  continuously reducing to form  $\dot{\text{C}}\text{O}$  (Eq. 46). Then  $\dot{\text{C}}\text{O}$  and  $\dot{\text{H}}$  radicals will bond to form C-H radicals to form CH<sub>4</sub> (Eq. 47-48) [74]. For the H<sub>2</sub>, CO, CH<sub>4</sub> and CH<sub>3</sub>OH heterolytic formation pathway, These product

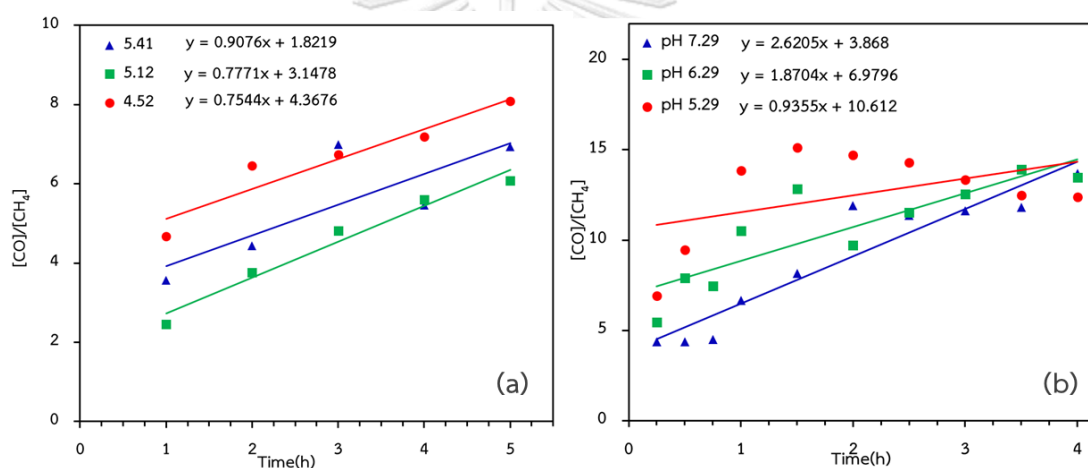

formation pathways, consisting of  $\dot{\text{CO}}_2^-$  and  $\text{H}^+$  binding has been proposed as shown in Table 2 or Eq. 50-52 [75].

If the rate limiting step in  $\text{CO}_2$  photoreduction is the radical anion formation  $\dot{\text{CO}}_2^-$  (Eq. 44), the homolytic or heterolytic paths occur after this step; therefore, they cannot be distinguished kinetically. The intermediate formation of  $\dot{\text{CO}}_2^-$  is the rate limiting step for  $\text{CO}_2$  photocatalytic reduction [76], but the product yields depend on the reaction condition or the used solvent that promote faster pathways. In experiments, the water is the polar media that favoured for heterolytic intermediate formation pathway as Eq. 50-52. These product formations must follow the reduction potential of reaction. The  $\text{CO}_2$  photoreduction potential to  $\text{CO}$ ,  $\text{CH}_3\text{OH}$ ,  $\text{CH}_4$  and  $\text{H}_2$  are -0.52, -0.38, -0.34 and 0, respectively [77]. According to these values, the products partitioning order must be  $\text{H}_2 > \text{CH}_4 > \text{CH}_3\text{OH} > \text{CO}$ .

However,  $\text{CO}$  has a different order of product formation at all pH, as shown in Figure 17. In fact,  $[\text{CO}]/[\text{CH}_4]$  increases with time, as shown in Figure 18(a): therefore, additional  $\text{CO}$  formation is obtained with time meaning that there're is another pathway that contributes with additional  $\text{CO}$  formation. If there is only one  $\text{CO}$  pathway contribution,  $[\text{CO}]/[\text{CH}_4]$  ratio should be maintained constant with time. There is also

an initial increase of the  $[H_2]/[CH_4]$  ratio that was increased in the initial period and turn back to  $t_0$  ratio (Figure 18(b)). The alternative pathway formation for CO and  $H_2$  production reaches a maximum contribution at 3 h. After that time, ratios return to the initial ratio at  $t_0$  (Figure 18(a, b)). The  $t_0$  contributions are given by estimating the intersection straight lines to  $t = 0$ . These ratio values are 1.8, 3.1 and 4.3 at pH = 5.12, 5.41 and 4.51, respectively for  $[CO]/[CH_4]$  and 1.7 for  $[H_2]/[CH_4]$ . This means that  $CH_4$  selectivity ( $[CO]/[CH_4]$  at  $t_0$ ) increases at lower pH. From the maximum ratio in Figure 18, the alternative pathway contribution can also be estimated. From these maximum values, it can be concluded that CO is produced twice as a large amount as  $H_2$ .

**Figure 18** CO<sub>2</sub> Photoreduction products ratios of (a).  $[CO]/[CH_4]$  and (b).  $[H_2]/[CH_4]$  Vs. reaction time by P25 performing at different pH.

According to Figure 19, the proposed photoreduction mechanism in the gas phase is limited by the  $\dot{CO}_2^-$  radical anion formation formed via previous equilibrium of direct addition of reactant molecule to  $TiO_2$ . However, in the aqueous phase is limited by carbene formation ( $R-\ddot{C}-R$ ) via previous equilibrium [1]. The radical anion and the carbene pathway finally form CO,  $H_2$ ,  $CH_4$  and  $CH_3OH$ . According to the  $[CO]/[CH_4]$  and  $[H_2]/[CH_4]$  ratios at  $t = 0$ , partitioning to CO is favored in a ratio 2-4. However, a contribution from the oxygen vacancies sites ( $O_v$ ) also occurs at early reaction times

(Figure 20) to produce 2 moles of CO and 1 mole of H<sub>2</sub> [78] by adding oxygen from reactant to V<sub>0</sub>, as experimental ratios of Figure 18. From Figure 19, the partitioning 3 produces formate radical anion that has been detected by EPR [79]. It is formed via homolytic rupture of the O-C bond and heterolytic cleavage of the O-H bond at the radical anion adduct.

**Figure 19** Reaction mechanism and kinetic ( $t_0$ ) path for CO, H<sub>2</sub>, CH<sub>4</sub> and CH<sub>3</sub>OH formation. Partitioning 2 is acid catalyzed. [CO]/[CH<sub>4</sub>] increases when decreasing pH.

Formate radical anion  $\dot{\text{C}}\text{O}_2^-$  (partitioning 3) has been detected by EPR [79]

**Figure 20** Top: Oxygen vacancies (O<sub>v</sub>) produced by O<sub>2</sub> evolution promoted by light at the TiO<sub>2</sub> VB. Bottom: Additional path for CO and H<sub>2</sub> formation at the P25 oxygen vacancies. A 2:1 CO: H<sub>2</sub> is produced at early reaction times after t=0 until a maximum [CO]/[CH<sub>4</sub>] is reached [37].

### 4.3 HCO<sub>3</sub><sup>-</sup> photoreduction experiments

HCO<sub>3</sub><sup>-</sup> Photoreduction on P25 catalyst kinetic experiments were conducted. It has been proposed that using HCO<sub>3</sub><sup>-</sup> as reactant CO, CH<sub>4</sub> and CH<sub>3</sub>OH (Eq. 29-30) are produced [80]. Therefore, NaHCO<sub>3</sub> solid has been used in this work in order to obtain better controlled conditions of the system studied. The sodium cation (Na<sup>+</sup>) from NaHCO<sub>3</sub> dissolution has been reported that no effects on the photoreactions are observed [81] because Na<sup>+</sup> is not favored to adsorb on the TiO<sub>2</sub> [82]. Consequently, the HCO<sub>3</sub><sup>-</sup> photocatalytic reduction was studied under different initial concentrations ([HCO<sub>3</sub><sup>-</sup>]<sub>0</sub> = 11.9-71.4 × 10<sup>3</sup> nmol/ml) and pH conditions (pH = 5.29-7.29). Considering similar conditions, the production rate of CH<sub>4</sub>, H<sub>2</sub> and CO from initial concentration [HCO<sub>3</sub><sup>-</sup>]<sub>0</sub> = 23.8 × 10<sup>3</sup> nmol/ml at pH = 5.29 are more than about 5 times with [CO<sub>2</sub>]<sub>0w</sub> = 34 × 10<sup>3</sup> nmol/ml at pH = 5.41. It can be concluded that using HCO<sub>3</sub><sup>-</sup> the same products as when using CO<sub>2</sub> are formed but rates are faster.

**Figure 21** Production rate of  $\text{HCO}_3^-$  photoreduction on P25 under  $[\text{HCO}_3^-]_0 = 23.8 \mu\text{mole/ml}$  ( $23.8 \times 10^3 \text{ nmol/ml}$ ), different pH, Temperature  $45^\circ\text{C}$ .

Both  $\text{CO}_2$  and  $\text{HCO}_3^-$  photoreduction must form  $\cdot\text{CO}_2^-$  radical anion before going to the next step (Eq. 44 and Eq. 29-30 for  $\text{HCO}_3^-$  cases). So, the rate limiting step of both cases is the formation of  $\cdot\text{CO}_2^-$ . The different production rate must be due to the adduct formation or/and the electron transfer from Ti. As shown in Figure 22, the adduct formation on  $\text{TiO}_2$  surface in both  $\text{CO}_2$  and  $\text{HCO}_3^-$  photoreduction is similar. Thus, the production rate changing is not due to the electron transfer rate (k). The  $\text{CO}_2$  hybridization is changed from  $sp$  to  $sp^2$ , when using  $\text{CO}_2$  as the substrate[83]. On the other hand, the  $\text{HCO}_3^-$  hybridization was not changed. The different production rate between using  $\text{HCO}_3^-$  and  $\text{CO}_2$  causes the OH on Ti was substituted to produce  $\text{H}_2\text{O}$  during adduct formation in  $\text{HCO}_3^-$  case. Consequently, the different production rate between  $\text{CO}_2$  and  $\text{HCO}_3^-$  cases must come from the adsorption equilibrium constant (K).

**Figure 22** Adsorption equilibrium ( $K$ ) and the rate constant of radical anion formation ( $k$ ) for bicarbonate and carbon dioxide [83].

$$\text{Rate} = \text{d}[\text{CO}_2]_{\text{w}}/\text{dt} = 1/8\text{d}[\text{H}^+]/\text{dt} = \text{kK}[\text{CO}_2]_{\text{w}}/(1 + \text{K}[\text{CO}_2]_{\text{w}}) \quad \text{Eq. 54}$$

Eq. 53 shows overall reaction to produce one molecule of  $\text{CH}_4$ , from  $\text{CO}_2$ ; 8 moles of  $\text{e}^-$  and 8 electrons of  $\text{H}^+$  in photoreduction are consumed. However,  $\text{CO}_2$  or  $\text{HCO}_3^-$  adsorption on  $\text{TiO}_2$  as Figure 22 shows must occur before  $\text{CO}_2$  or  $\text{HCO}_3^-$  further reduction. Langmuir-Hinshelwood (LH) is an approach that could be used as a kinetic model. According to Eq. 54, the equilibrium constant of  $\text{HCO}_3^-$  adsorption ( $K$ ) and the rate constant of  $\text{CH}_4$  formation ( $k$ ) at maximum adsorbed  $\text{HCO}_3^-$  on  $\text{TiO}_2$  surface ( $\text{HCO}_3^-$ - $\text{TiO}_2$ ) can be obtained from the production rate results under different pH conditions. At the range of pH 5.29- 7.29 used  $\text{HCO}_3^-$  is the main species in solution [7], meanwhile,  $\text{TiO}_2$  surface charge changes in this pH range.  $\text{TiO}_2$  surface is mainly positive (+) charge at pH 5.29, neutral or zero (0) charge at pH 6.29 and negative charge (-) at pH 7.29. Therefore, the constant values of  $k$  and  $K$  for the kinetic model under each  $\text{TiO}_2$  charge surfaces can be obtained under different initial concentrations. The  $\text{CH}_4$  rate formation under  $[\text{HCO}_3^-]_0 = 11.9\text{-}71.434 \mu\text{mole}/\text{mL}_{\text{H}_2\text{O}}$  at each pH 5.29-7.29 are showed in Figure 23. According to Eq. 54, the  $k$  and  $K$  values were obtained from the

plot of  $1/\text{rate}$  versus  $1/[\text{HCO}_3^-]_0$ , as shown in Figure 24, which  $1/Kk = k_{\text{obs}}$  values were obtained from line slopes and  $1/k$  from the intercept.

**Figure 23**  $[\text{CH}_4]$  versus  $t$  plots obtained in the P25 photoreduction of  $[\text{HCO}_3^-]_0 =$  (a) 11.9, (b) 23.8, (c) 47.6 and (d) 71.4  $\mu\text{mole/ml}$  at temperature 45 °C.

The equilibrium constant of  $\text{HCO}_3^-$  adsorption ( $K$ ) and the rate constant of  $\text{CH}_4$  formation ( $k$ ) change according to charge surface types of  $\text{TiO}_2$  at pH used (pH = 5.29(+), 6.29(0) and 7.29(-)). The trend of adsorption constant are  $K(0) > K(-) > K(+)$  and the rate constant of  $\text{CH}_4$  formation are  $k(+)> k(-) > k(0)$ . In Figure 25, the relative stabilities of  $\text{TiO}_2\text{-HCO}_3^-$  adduct and the radical anion formation at the neutral, positive and negative charge surface are shown. The  $\text{HCO}_3^-$  is better adsorbed on the neutral charge surface (0) than in the negative charged surface (-), due to negative charges repulsion at the negative site of  $\text{HCO}_3^-$  [84]. Meanwhile, the  $\text{HCO}_3^-$  adsorbs less on positive charged surface, as expected since bicarbonate is attacked from the  $\text{H}_2\text{O}^+$ , a poor nucleophile [85].

On the contrary, the rate constant of  $\text{CH}_4$  formation ( $k$ ) that involves  $e^-$  transfer to form radical anion, was favoured on the positive charged surface. It indicates that the electrostatic interaction between  $\text{H}_2\text{O}^+$  stabilizes the radical anion formation  $\text{HCO}_3^-$ . However, the radical anion formation was better stabilized on the negative charge surface when compare to the neutral charge surface, due to delocalization occur and form the di-anionic [86]. These  $\text{HCO}_3^-$  photoreduction results could be concluded that the neutral charged surface was more effective when considering the  $k_{\text{obs}}$  ( $kK$ ) value. Although the positive charged surface (pH = 5.29) provide faster electron transfer rate, it provide the lowest adsorption efficiency.

**Figure 25**  $\text{TiO}_2\text{-HCO}_3^-$  adducts and corresponding radical anions relative stabilities at neutral, positive and negative charged  $\text{TiO}_2$  surface [84, 85].

#### 4.4 Changing P-25 morphology

It has been reported [84] that the morphology of catalyst affects the photoactivity. For P25 catalyst, using only one phase whether it be anatase or rutile phase it exhibited low activity. However, the coupling between 2 phases can improve the activity of photoreaction and get higher yield of products. A cooperative performance is then expected. The coupling phases in  $\text{TiO}_2$  may be promoted by the sonication of P25 [87]. Under the same condition ( $[\text{HCO}_3^-]_0 = 71.4 \times 10^3 \text{ nmol/ml}_{\text{H}_2\text{O}}$ ,  $\text{pH} = 5.29$  and temperature  $45^\circ\text{C}$ ). As shown in Figure 26  $\text{CH}_4$  formation rate using original P25 catalyst (P25) is  $2.80 \text{ nmol/ml}_{\text{H}_2\text{O}}\text{Scat.h}$ . The sonicated P25 catalyst (Sonic.P25) has about 4 times faster rate and  $\text{CH}_4$  selectivity is also increased as shown in the  $[\text{CO}]/[\text{CH}_4]$  plot (Figure 27). Although the  $[\text{CO}]/[\text{CH}_4]$  of P25 and Sonic.P25 were similar at the beginning time ( $t_0$ ),  $[\text{CO}]/[\text{CH}_4]$  of P25 increases with time, while the  $[\text{CO}]/[\text{CH}_4]$  of Sonic.P25 is steady. This means that the Sonic.P25 does not have another alternative pathway that produces more CO as when original P25 is used. It is proposed that Sonic.P25 performed only by the main mechanism (Fig. 19) to produce products without the involvement of oxygen vacancies ( $\text{O}_v$ ) which lead to more CO production. Regularly, the  $\text{O}_v$  act as the  $e^-$  trap that inhibits the  $e^-/h^+$  recombination but the  $\text{O}_v$  can detain the  $e^-$  in the trap steadily and delay the  $e^-$  transfer the electrolyte. In the one phase performance (Figure 20), the  $\text{O}_v$  preferentially direct  $e^-$  to reduce reactant and to fulfill the oxygen in vacancies. This oxygen replenishment leads to more CO production. After sufficient replenishment, the alternative formation path as Figure 20 will return to the normal path as Figure 19. On the other hand, the  $\text{O}_v$  in Sonic.P25 provides a superior photoactivity. In addition to the co-working of narrow bandgap between anatase and rutile phases cause better electron hierarchical transfer, the  $\text{O}_v$  in the coupling between phases reduces recombination and promote electron transfer from anatase conduction band. In addition to the co-working of narrow bandgap between anatase and rutile phases cause better electron hierarchical transfer. The  $e^-$

of rutile phase move to anatase Ov from where it combines with anatase phase hole ( $h^+$ ); therefore, anatase excited  $e^-$  can be transfer to the electrolyte faster since its recombination with its hole is minimized, as shown in Figure 28. This effect explains the faster  $CH_4$  formation rate and its selectivity increment.

Figure 26 (a).  $CH_4$  and (b).  $CO$  formation rate of  $HCO_3^-$  photoreduction on the P25 and Sonic.P25 catalysts under  $[HCO_3^-]_0 = 71.4 \mu\text{mol/ml}$  and pH 5.29.

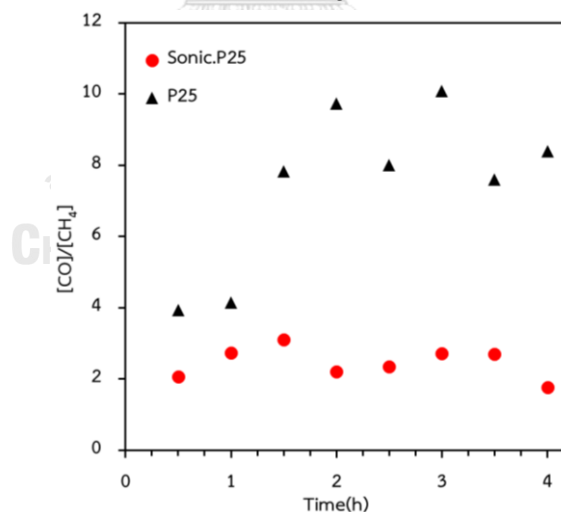

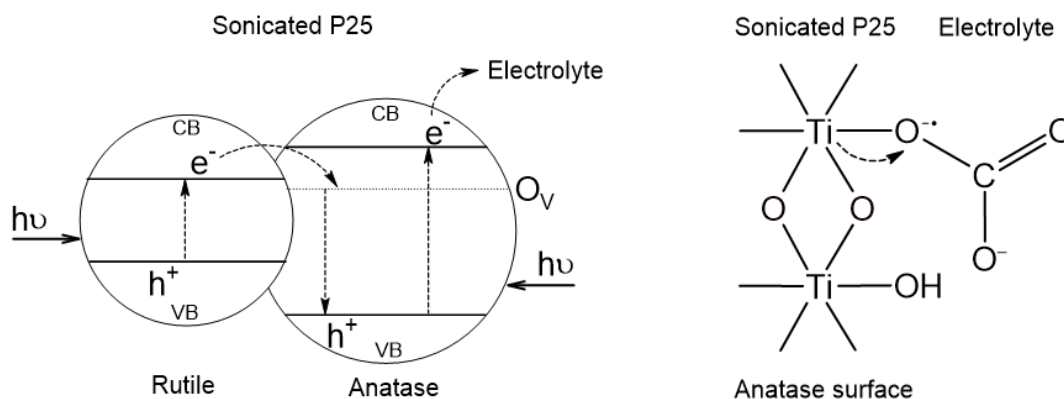

Figure 27  $[CO]/[CH_4]$  versus time plots of produced products concentration from  $HCO_3^-$  photoreduction on the P25 and Sonic.P25 catalysts.

**Figure 28** The electron transfer to the electrolyte in the coupling narrow band gap between anatase and rutile phases and its oxygen vacancy

#### 4.5 [CO]/[CH<sub>4</sub>] ratios and alternative CO pathway formation

The [CO]/[CH<sub>4</sub>] ratios versus time plots are shown in Figure 19 and 29. [CO]/[CH<sub>4</sub>] ratios increase at the beginning period with a further stabilization (fulfill oxygen vacancy). There is just one mechanism pathway for CH<sub>4</sub> and CO formation if the ratio is constant with reaction time. However, if there is CH<sub>4</sub> and CO equilibrium or if there is an alternative pathway, ratio changed with time. From the ratio plots of Figure 29, it increased in the beginning period and decreased after 2 hours of reaction time. Therefore, the alternative pathway was causing the changing of [CO]/[CH<sub>4</sub>] ratios. The straight line intersection ratio at  $t=0$  were the [CO]/[CH<sub>4</sub>] ratio without an alternative pathway. Furthermore, the [CO]/[CH<sub>4</sub>] ratio increases faster at lower pH condition. This means that the acid condition could promote the CO alternative pathway, just as it is indicated in Figure 20 (bottom).

As shown in Figure 20, the interaction of O<sub>v</sub> with HCO<sub>3</sub><sup>-</sup>-TiO<sub>2</sub> may produce CO by fulfill O<sub>v</sub> as reported for CO<sub>2</sub> case [88]. The O<sub>v</sub> occupation in the alternative pathway may deactivate the activity of P25. However, the P25 activity could be reactivated by creating new O<sub>v</sub> during photocatalytic reduction.

**Figure 29** The  $[\text{CO}]/[\text{CH}_4]$  ratio versus time plot obtained by  $\text{HCO}_3^-$  photoreduction on P25 catalyst under UV irradiation, temperature  $45^\circ\text{C}$ ,  $[\text{HCO}_3^-]_0 = 23.8 \mu\text{mol/ml}$  at three different pH.

#### 4.6 $\text{H}_2\text{O}/\text{D}_2\text{O}$ solvent isotope effect

$\text{H}_2\text{O}$  is an important solvent for  $\text{HCO}_3^-$  photoreduction since it provides protons required. Solvent isotope effects were studied to prove the importance and possibility of solvent in the rate limiting step of photoreduction. The solvent isotope effect can be observed by changing the used isotope solvent from  $\text{H}_2\text{O}$  to  $\text{D}_2\text{O}$ . Changing the transfer of H to D in the rate limiting step, as shown in Figure 31. Isotope change may also affect the equilibrium for adduct formation since it shifted to the left when using  $\text{D}_2\text{O}$  because  $\text{OD}^-$  is more basic than  $\text{OH}^-$  about two times. Likewise, the  $\text{LCO}_3^-$  substrate promote changing of the equilibrium K when  $\text{DCO}_3^-$  and  $\text{HCO}_3^-$  are used [89], balancing the equilibrium isotope change. Therefore, the transfer of protons  $\text{L}^+$  from  $\text{L}_2\text{O}$  in rate-limiting step may be the main contribution to the the solvent isotope effect observed. From the experimental results, the solvent isotope effect can be determined by comparing the product rate of  $\text{CH}_4$ ,  $\text{CO}$  and  $\text{H}_2$  when using  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  as solvent.

KIEs =  $\text{rate}_{\text{H}_2\text{O}}/\text{rate}_{\text{D}_2\text{O}} = k_{\text{obs}}(\text{H}_2\text{O})/k_{\text{obs}}(\text{D}_2\text{O}) = 1.38$  for  $\text{CH}_4$ , 1.4 for  $\text{CO}$  and  $\text{H}_2$  formation are obtained. The experiment is operated on P25 under the negative charge surface condition ( $\text{pH} > 7.5$ ). Therefore, L transfer at the transition state ( $e^-$  transfer step) must come from water. The obtained KIEs are not larger due to L position in  $\text{L}_2\text{O}$  donor, and  $\text{C}=\text{O}$  acceptor is not symmetric. The small solvent isotope effect observed for  $\text{H}_2$  formation indicates that  $\text{L}^+$  reduction to  $\text{L}_2$  on the  $\text{TiO}_2$  surface is minimum in the photoreduction [90].

**Figure 30** Solvent  $\text{H}_2\text{O}/\text{D}_2\text{O}$  isotope effect in the rates of (a)  $\text{CH}_4$ , (b)  $\text{H}_2$  and (c)  $\text{CO}$  formation from  $\text{HCO}_3^-$  photoreduction on P25 under UV irradiation,  $[\text{HCO}_3^-]_0 = 23.8 \mu\text{mol/ml}$ , Temperature  $45^\circ\text{C}$ .

**Figure 31** Solvent isotope effect at the equilibrium ( $K$ ) and transition state ( $k$ ) of products common intermediate (radical anion) formation.

## CHAPTER V

### CONCLUSION AND RECOMMENDATION

#### 5.1 Conclusion

CO<sub>2</sub> photoreduction in aqueous phase on P25 (TiO<sub>2</sub>) operated under UV light irradiation produces 9% CH<sub>4</sub>, 65% CO, 25% H<sub>2</sub> and 1% CH<sub>3</sub>OH with very low conversion  $7 \times 10^3$  % for CH<sub>4</sub>. The production rates are limited by TiO<sub>2</sub>-CO<sub>2</sub> adduct radical anion intermediate formation. Partitioning of this intermediate produces CH<sub>4</sub> and CH<sub>3</sub>OH through carbene intermediate path; meanwhile, CO and H<sub>2</sub> are also produced from the same radical anion partitioning. [CO]/[CH<sub>4</sub>] and [H<sub>2</sub>]/[CH<sub>4</sub>] ratios plot increase with time, therefore there is an alternative path at O<sub>v</sub> in P25, which promote CO and H<sub>2</sub> production that decreases CH<sub>4</sub> selectivity. The O<sub>v</sub> can be produced by TiO<sub>2</sub> self-oxidation in VB. HCO<sub>3</sub><sup>-</sup> photoreduction has same rate limiting step as CO<sub>2</sub> and proceeds through a mechanism via LH mechanism. In the same conditions, the production rate when using HCO<sub>3</sub><sup>-</sup> as the reactant is faster than when using CO<sub>2</sub>. Bicarbonate adsorption equilibrium to form TiO<sub>2</sub>-HCO<sub>3</sub><sup>-</sup> is larger due to the hybridization change from sp to sp<sup>2</sup> in CO<sub>2</sub> case. LH kinetic model allows to obtain, K and k values depending on the charge surface species of TiO<sub>2</sub>, which can be controlled by changing pH conditions: positive (+, pH 5.29), neutral (0, pH 6.29) and negative (-, pH 7.29) charge surfaces. The trend of the adsorption equilibrium constant is K(0) > K(-) > K(+) and the rate constant k is k(+) > k(-) > k(0). It means that HCO<sub>3</sub><sup>-</sup> adsorbs better on the neutral and negative charge surface; meanwhile the positive charge surface attack HCO<sub>3</sub><sup>-</sup> inhibits adduct formation. As opposed to the electron transfer rate (k) is favored in low pH condition due to stability of formed radical anion on the positive charge surface. The [CO]/[CH<sub>4</sub>] and [H<sub>2</sub>]/[CH<sub>4</sub>] ratios in the HCO<sub>3</sub><sup>-</sup> photoreduction increase at the initial period, meaning that more CO and H<sub>2</sub> are produced by an alternative pathway via O<sub>v</sub>. The solvent isotope effect, KIEs value of rate<sub>H<sub>2</sub>O</sub>/rate<sub>D<sub>2</sub>O</sub> = 1.4 is observed for CH<sub>4</sub>, and CO and H<sub>2</sub>

formation. It confirms that the radical anion adduct formation is a common rate limiting step for all products detected in the photoreduction.

Low absorption on P25 can be improved by increasing pH condition. However, the  $e^-/h^+$  recombination in anatase phase inhibits the electron transfer to the electrolyte, and its  $O_V$  tends to decrease  $CH_4$  selectivity. Sonicated P25 increases the production rate and selectivity of  $CH_4$ , since loading anatase on the rutile phase promotes reactants adsorption and charge separation and reduce trapped electron from  $O_V$  to be transferred to the electrolyte.

## 5.2 Recommendation

1. Develop a process for continuous flow.
2. Using other buffers that can accelerate the photocatalytic reaction.

## APPENDIX A

## CALCULATION OF THE CRYSTALLITE SIZE

Calculation of the crystallite size by Debye-Scherrer equation. The crystallite size can be calculated from  $2\theta$  profile analysis, the half-height width of diffraction peak using the Debye-Scherrer equation.

From Scherrer equation: 
$$D = \frac{k\lambda}{\beta \cos\theta}$$
 Eq. 55

Where

$D$  = Crystallite size (Å)

$k$  = Crystallite-shape factor (0.9)

$\lambda$  = X-ray wavelength (1.5418 Å for  $\text{CuK}\alpha$ )

$\beta$  = X-ray diffraction broadening (radian)

$\theta$  = Observed peak angel (degree)

The X-ray diffraction broadening ( $\beta$ ) can be obtained by using Warren's formula

Warren's equation: 
$$\beta^2 = \beta_M^2 - \beta_S^2$$
 Eq. 56

$$\beta = \sqrt{\beta_M^2 - \beta_S^2}$$
 Eq. 57

Where  $\beta_M$  = Measured peak width in radians at half peak height

$\beta_S$  = Corresponding width of a standard material

Example: Calculation of the crystallite size of P25-TiO<sub>2</sub>.

Finding the half-weight width (101) diffraction peak at 25.3° from the XRD pattern

The half-weight width (101) diffraction peak;

$$\beta_M = 0.3959 \text{ degree}$$

$$\beta_S = 0.0069 \text{ radian}$$

The corresponding half-height width of the peak of P25-TiO<sub>2</sub>

$$\beta_S = 0.003836 \text{ radian}$$

The pure width 
$$\beta = \sqrt{\beta_M^2 - \beta_S^2}$$

$$\beta = \sqrt{0.0069^2 - 0.0038^2}$$

Where  $\lambda = 1.54 \text{ \AA}$

$\beta = 0.00575$  radian

$\theta = 12.65$  degree

The crystallite size:

$$D = \frac{k\lambda}{\beta \cos\theta}$$
$$D = \frac{(0.9)(1.54)}{(0.00575)\cos(12.65)}$$
$$= 241.89 \text{ \AA} = 24.19 \text{ nm}$$

## APPENDIX B

## CALCULATION OF WEIGHT COMPOSITION

The weight fraction of P25-TiO<sub>2</sub> was calculated from the XRD pattern.

$$W_A = \frac{K_A A_A}{K_A A_A + K_B A_B + K_R} \quad \text{Eq. 58}$$

$$W_B = \frac{K_B A_B}{K_A A_A + K_B A_B + K_R} \quad \text{Eq. 59}$$

$$W_R = \frac{K_R}{K_A A_A + K_B A_B + K_R} \quad \text{Eq. 60}$$

Where

$W_A$  = Weight fraction of anatase phase TiO<sub>2</sub>

$W_B$  = Weight fraction of brookite phase TiO<sub>2</sub>

$W_R$  = Weight fraction of rutile phase TiO<sub>2</sub>

$A_A$  = The intensity of anatase peak

$A_B$  = The intensity of brookite peak

$A_R$  = The intensity of rutile peak

$K_A$  = The coefficient factor of anatase (0.886)

$K_B$  = The coefficient factor of brookite (2.721)

The phases of TiO<sub>2</sub> can be calculated from the integrated intensities of the peak at  $2\theta = 25.3^\circ$  (anatase phase), the peak at  $27.4^\circ$  (rutile phase), and the peak at  $30.6^\circ$  (brookite phase). However, P25 catalyst consisted of anatase phase and rutile phase except for brookite phase.

Example: Calculation of the phase composition of P25-TiO<sub>2</sub>.

Where The integrated intensities of anatase ( $A_A$ ) = 2297.4

The integrated intensities of rutile ( $A_R$ ) = 449.3

## APPENDIX C

## CALCULATION OF THE ENERGY BAND GAP FROM UV-VIS SPECTRA

From the UV light absorbance results at various wavelengths from 200 - 800 nm by UV - VIS Spectrophotometer. The absorption values at each wavelength were used for the energy bandgap calculation.

$$hv\alpha = \text{const}(hv - E_{bg})^n \quad \text{Eq. 61}$$

where  $h$  is Plank's constant =  $4.13566743 \times 10^{-15}$  eV.s

$\nu$  is Light frequency (1/s)

$\alpha$  is optical absorption coefficient

$c$  is Speed of light = 299,792,458 m/s หรือ  $2.997924 \times 10^8$  nm/s

$n$  is Material constant of sample

$E_{bg}$  is Energy band gap of catalyst (eV)

Example: The energy band gap calculation of P25 catalyst. From light absorption result at 400 nm wavelength, absorbance constant is 3.0996.

Then;  $\lambda = 400$  nm,  $\alpha = 0.186$ ,  $h = 4.13566743 \times 10^{-15}$  eV.s,  $c = 299,792,458$  m/s หรือ  $2.997924 \times 10^{17}$  nm/s and  $n = 1/2$  for solid.

Therefore;  $h\nu = hc / \lambda$

$$h\nu = (4.13566743 \times 10^{-15} \text{ (eV.s)} \times 2.997924 \times 10^{17} \text{ (nm/s)}) / 400 \text{ (nm)}$$

$$h\nu = 3.0996 \text{ eV}$$

If;  $K = \alpha / \text{const}$  ;assume const =1

$$(K.h\nu)^2 = (0.186 \times 3.0996 \text{ eV})^2 = 0.3324$$

Calculate the  $h\nu$  and  $(K.h\nu)^2$  values at each wavelength, then the  $h\nu$  and  $(K.h\nu)^2$  plot is used for energy band gap extrapolation. From Figure 33, the straight-line cut the X-axis presented the band gap energy of pure P25 is 3.27 eV.

Figure 32 A plot between  $(K.h\nu)^2$  vs. photon energy ( $h\nu$ ) of P25

## VITA
