## APPENDIX A

### Sample of Calculation

#### A.1 Calculation of Designed Metal Loading for Catalyst Preparation.

The sample of calculation shown below is for 28V-Mg-O catalyst.

Aqueous solution consists of  $\text{NH}_4\text{VO}_3$  0.5 wt%  
 $\text{NH}_3\text{OH}$  1.0 wt%

Volume of solution is designed to be 100 ml., hence  $\text{NH}_4\text{VO}_3$ ,  $\text{NH}_3\text{OH}$  and  $\text{H}_2\text{O}$  are weighted for 0.5, 1.0, and 98.5 gram respectively.

The amount of MgO powder for 28%(by weight) vanadium oxide in V-Mg-O catalyst is calculated as follows:

if the weight of catalyst is 100 gram,

28V-Mg-O would compose of  $\text{V}_2\text{O}_5$  28 g. and MgO 72 g.,

therefore in this system (compose of  $\text{V}_2\text{O}_5$  0.5 g.),

the amount of MgO =  $72/28 * 0.5 \approx 1.2857$  g.

therefore there is vanadium oxide on MgO support =  $0.5/(0.5+1.2857) * 100$   
 = 28 wt%

## APPENDIX B

### Calculation of Flow Rate and Explosive Limit

B.1 Calculation of Flow of  $C_3H_8$ , air and argon with varying HC/ $O_2$  Mole ratio.

The calculation shown below is for feed composition of 4 vol% propane, 8 vol% oxygen and the balance argon:

for total flow = 100 ml./min.

flow of 21%  $O_2$  in air is assumed to be X ml./min.

flow of 20%  $C_3H_8$  in  $N_2$  is assumed to be Y ml./min.

if the feed contains 8 vol% oxygen,

then there is  $O_2$  in flow of  $O_2$  in air =  $21X/100 = 8$

also there is  $C_3H_8$  in flow of  $C_3H_8$  in  $N_2$  =  $20Y/100 = 4$

therefore X = 38.09 ml./min.

Y = 20 ml./min.

argon used as balance gas, hence its flow is equal to  $100 - 38.09 - 20$

= 41.91 ml./min.

ศูนย์วิทยทรัพยากร  
 จุฬาลงกรณ์มหาวิทยาลัย

## B.2 Calculation of explosive limit of propane in air.

The explosive limit of propane in air are shown below [82],

|         | lower limit in air | upper limit in air |
|---------|--------------------|--------------------|
| propane | 2.37 vol%          | 9.5 vol%           |

Therefore, the amount of propane in the feed must not be in the range of this explosive limit (between 2.37-9.5 % in air).

Sample of calculation for the condition of feed stream 4:8:88,

flow rate  $C_3H_8$  used in this study is fixed to 4 ml./min.

flow rate of air is 38.09 ml./min.

hence, there is propane in air =  $4/38.09 * 100$   
 = 10.50% (this value is O.K.)

 จุฬาลงกรณ์มหาวิทยาลัย

## APPENDIX C

## Chemisorption at Oxide Surfaces [29]

Table C.1 Classification of heterogeneous catalysts [29]

| Class                                     | Functions  | Examples   |
|---|--|--|
| Metals                                    | hydrogenation  |  |
|   | dehydrogenation  | Fe, Ni, Pd, Pt, Ag   |
|   | hydrogenolysis<br>(oxidation)                          |  |
| Semiconducting<br>oxides and<br>sulphides | oxidation  |  |
|   | dehydrogenation<br>desulphurization<br>(hydrogenation) | NiO, ZnO, MnO <sub>2</sub> ,<br>Cr <sub>2</sub> O <sub>3</sub> , Bi <sub>2</sub> O <sub>3</sub> -MoO <sub>3</sub> ,<br>WS <sub>2</sub> |
| Insulator oxides                          | dehydrogenation  | Al <sub>2</sub> O <sub>3</sub> , SiO <sub>2</sub> , MgO  |
| Acids                                     | polymerization   |  |
|   | isomerization  | H <sub>3</sub> PO <sub>4</sub> , H <sub>2</sub> SO <sub>4</sub> ,  |
|   | cracking<br>alkylation                                 | SiO <sub>2</sub> -Al <sub>2</sub> O <sub>3</sub> , zeolites  |

Table C.1 shows the kinds of reaction catalysed by oxides depending upon whether the oxide is a semi-conductor or an insulator. It is now time to try to explain these terms and to seek a rationalization of catalytic behavior in terms of the chemisorption of molecules on oxide surfaces. The problem is in some ways more difficult than for metals for several reasons [29]:

- 1) there is the simple fact that the surface contains two types of species, anions and cations, and in general their relative amounts and steric disposition will

vary from one crystal plane to another. It has to be established whether both species participate in a given chemisorption.

2) Oxides differ greatly from one another in their thermal stability. Those of the pre-transition elements, the so-called ceramic oxides, are remarkably stable and find numerous high-temperature applications, while those of the transition and post-transition elements in general lose oxygen under vacuum, especially when heated. For this reason, and because they are not electrical conductors, they are not so easy to study by the physical techniques that have proved rewarding in the case of metals. Less is therefore known about the adsorbed states of molecules on oxides.

3) Many, indeed most, of the oxides used as catalysts in practice are in fact binary or more complex mixtures of oxides. It is difficult to define their surface composition, and fundamental studies of chemisorption on them require extremely careful work. Further complications will appear in due course.

To understand more about the chemisorption properties of oxides, and the reactivity of their surfaces, it is necessary first to know more about what happens below the surface. It has long been recognized that the mobility of electrons within a solid gives useful information about the nature of the chemical bonds that it contains. The following theory is the examination about the electrical conductivities of solids. This in turn will assist the understanding of chemisorptive and catalytic properties of oxide surfaces.

### C.1 Electrical Conductivity of Solids

On the basis of their electrical conductivities, solids are traditionally divided into four classes as shown in Table C.2. Superconduction is only shown by metals at very low temperatures, and they are included simply to emphasize the astonishing range of 55 orders of magnitude over which electrical conductivity can be measured. There are two classes of semiconductors. Group III-GroupV

compounds like gallium arsenide, are termed *intrinsic* semiconductors because their conductivity is an inherent feature of their chemical structure. However, important as these substances are in solid state devices, they are not catalytically active and will not be considered further. The greater interest are the oxides and sulphides whose conduction is due to their departure from precise stoichiometry: these substances are termed *extrinsic* or defect semiconductors. The more non-stoichiometric they are, the greater their conductivities increase with temperature according to a relation similar to the Arrhenius equation, so that a straight line is obtained on plotting  $\log(\text{conductivity})$  against reciprocal absolute temperature.

**Table C.2** Classification of solids by electrical conductivity [29]

| Class           | Conductivity range ( $\Omega \text{ cm}^{-1}$ ) | Chemical class  | Examples   |
|-----------------|---|---|--|
| Superconductors | up to $10^{35}$                                 | metals at low temperatures                                      | -  |
| Conductors      | $10^4 - 10^6$                                   | metals and alloys   | Na, Ni, Cu, Pt etc.  |
| Semiconductors  | $10^3 - 10^{-8}$                                | (a) intrinsic:  |  |
|                 |   | semi-metals   | Ge, Si, GaAs, etc.   |
|                 |   | (b) extrinsic:  |  |
|                 |   | oxides and sulphides of transition and post-transition elements | ZnO, $\text{Cu}_2\text{O}$ , NiO, ZnS, $\text{MoS}_2$ , NiS etc. |
| Insulators      | $10^{-9} - 10^{-20}$                            | Stoichiometric oxides   | MgO, $\text{SiO}_2$ , $\text{Al}_2\text{O}_3$ etc.               |

Now some oxides when heated in air becomes oxygen deficient: zinc oxide is an example. Others like nickel oxide acquire oxygen, and become non-stoichiometric by having an excess of oxygen in the lattice.

## C.2 Chemisorption on Semiconducting Oxides

**Table C.3** Classification of semiconducting metal oxides [29]

| Effect of heating in air | Classification    | Examples   |
|--------------------------|-------------------|--|
| Oxygen lost              | Negative (n-type) | ZnO, Fe <sub>2</sub> O <sub>3</sub> , TiO <sub>2</sub> , CdO,<br>V <sub>2</sub> O <sub>5</sub> , CrO <sub>3</sub> , CuO, |
| Oxygen gained            | Positive (p-type) | NiO, CoO, Cu <sub>2</sub> O, SnO,<br>PbO, Cr <sub>2</sub> O <sub>3</sub>   |

A qualitative understanding of the chemisorption of simple gases on semiconducting oxides follows simply from their chemistry as the band theory of solid [5]. Reducing gases such as hydrogen and carbon monoxide are adsorbed strongly, but irreversibly; on heating, only water and carbon dioxide respectively can be recovered. Hydrogen probably dissociates heterolytically on adsorption, viz.

The hydroxyl ions will decompose on heating to form water and anion vacancies, and an equal number of cations will be reduced to atoms. Carbon monoxide usually chemisorbs first on the cation, whence it reacts with an oxide ion:

What is observed here is the first stage of a process that can lead ultimately to the complete reduction of the oxide to metal. These steps are also similar to those involved in the catalysed oxidation of these molecules.

The chemisorption of oxygen on p-type oxides which gain oxygen on heating in air occurs by a mechanism involving the oxidation of  $\text{Ni}^{2+}$  ions at the surface to  $\text{Ni}^{3+}$  :

High coverages by the  $\text{O}^-$  ion can result, and it is easy to see that this is the first step in the incorporation of excess oxygen, referred to above. When the n-type oxides which lose oxygen on heating in air (exemplified by zinc oxide) are exactly stoichiometric, they cannot chemisorb oxygen; when however they are oxygen-deficient, they can chemisorb just as much as is needed to restore their stoichiometry by refilling the anion vacancies and reoxidizing the zinc atoms. For the reasons mentioned at the beginning of this appendix, there is not the equivalent body of quantitative information concerning chemisorption on oxides that there is for metals. The principles just described will however be helpful towards rationalizing their catalytic behaviour.

### C.3 Adsorption on Insulator Oxides

Since the cations of insulator oxides can be neither oxidized nor reduced, they cannot chemisorb oxygen to any significant extent; they cannot chemisorb hydrogen or carbon monoxide for the same reason. They can, and do, react with water and other polar molecules as:

Indeed under normal circumstances the surfaces of oxides such as alumina and silica are covered by a layer of chemisorbed water; the surface is then said to be fully hydroxylated, and indeed these hydroxyl groups are very firmly bound. Their complete removal by heating is almost impossible. When the oxides are suspended in water the M-OH groups can dissociate either as acids or as bases, depending on the electronegativity of the cation, e.g.

The latter process will be seen later to be of value in the preparation of supported metal catalysts. Silica and alumina when well dried are useful desiccants, and alumina as well as other oxides such as titania are active catalysts for the dehydration of alcohols to alkenes because of their abilities to remove the elements of water from the reactant.
