D: Suwakul Chaiwarit : Novel Electrochemical Packed-Bed Reactor for Carbon Dioxide Reduction. Advisor: Asst. Prof. PALANG BUMROONGSAKULSAWAT

Electrochemical reduction of carbon dioxide (CO₂) is a promising strategy to recycle CO₂ into valuable chemical products. Nevertheless, a conventional apparatus which usually utilizes stack design to maximize its surface-to-volume ratio requires many elements and complicated instruction assembly. The stack design often requires feed streams to flow in narrow channels throughout the cell, which is also constrained by membrane size roughly 1 m² by current manufacture technology. This research focuses on development of a new type of electrochemical reactor that is suitable for industrial-scale applications. The novel electrochemical packed-bed reactor is designed for the electroreduction to convert CO₂ into CO in the gas phase. Humidified CO₂ was fed through the reactor, and a voltage was applied to the bed for initiate electrochemical reactions. The bed consists of 3 compartments including Zinc (Zn) deposited felt, ion-exchange resin, and platinized titanium arranged in this order. Effects of applied voltage and CO₂ flow rates toward the CO₂ reduction performance was investigated. The increasing of CO concentration and current were achieved with increasing voltage. The maximum CO concentration and the highest faradaic efficiency were observed at 6 V and 80 ml min⁻¹ for a single-cell bed. The optimal condition for a two-cell bed was 11 V and 120 ml min⁻¹. However, the effects of flow rate might oppose effects of mass transfer at high flow rate. An online infrared spectroscopy was coupled to the novel electrochemical packed-bed reactor for the CO product detection. The CO product analysis confirmed that the novel electrochemical packed-bed reactor successfully converts CO₂ to CO.

ACKNOWLEDGEMENTS

I would like to express my gratitude to my supervisor, Associate Professor Doctor Palang Bumroongsakulsawat, for his invaluable guidance, generous support, and additional ideas. I am very grateful to for all your help throughout the research. I am appreciated to a number of people who have assisted and supported me during my research: Malaysia-Thailand Joint Authority (MTJA) for their research fund, CECC supporting staffs for analytical instruments support, and Master degree student, Wongsatorn Wareprasert, for his assistance and ideas during the experiment.

Chapter 1

Introduction

1.1 Background

Fossil fuels have been utilized as a major energy source for a long time. The emission of greenhouse gases from carbon-based energy production combustion increased carbon dioxide (CO₂) concentration in the atmosphere and as a result, accelerated global warming (1). Consequently, the new technologies that minimize CO₂ accumulation and find new energy source has been investigated including storage, capturing, and conversion (2). These strategies have potential to recycle CO₂ into a profitable carbon source. Among them, the conversion of CO₂ is considered as an alternative energy source compared to among technologies because CO₂ can be converted to high energy small molecules such as carbon monoxide (CO) ,and hydrocarbons (3, 4). There are different CO₂ conversion strategies have been studied including electrochemical (5), photochemical (6), and thermochemical (7, 8). Among the other technologies, electrochemical strategies can be operated under ambient temperature and pressure (9). This strategy is also practical to adjust the energy of the active species to reach a high selectivity with precise control of the reaction pathway. Although, electrochemical CO₂ reduction has potential prospect, but its limitations have still to be addressed including the complexity of reduction pathway, high overpotential, and low current density. Thus, electrochemical reduction of CO₂ is vitally developed in catalyst and technology.

For high carbon-based products demands in industry, the selectivity of desire product is typically control by properties of metal electrode. Hori et al. (10) reported the variable selectivity of CO is depends on metal electrodes. To intensify catalytic properties, various methods have been used to improve the reduction performance such as modified surface, nano structuring (11, 12), and so on. However, the CO₂ reduction technologies is far from development to practical application. The CO₂ reduction systems are divided into two categories. The liquid phase system electrochemical reduction systems have been widely developed. However, CO₂ solubility is slightly which hinders CO₂ to interact with catalyst in liquid medium and difficult for scale-up (13). In contrast, electrochemical reduction in gas phase system are arising with the purpose of overcome mass transfer limitations happening in liquid phase and easier reactant mixing, which leads to the possibility to tune the CO₂/steam ratio, and recover product form reactant (14). Regardless, evaluating the performance of numerous electrodes in various electrolytes and different types of cells, at varying process parameters, is challenging.

In recent years, most of the studies focus on improve products selectivity by developed novel electrode, while there are a few attentions in reactors design and scale up. At first, fundamental CO₂ reduction research has been conducted in batch cell (H-cells). Nevertheless, H-cells are drawback because of mass transfer limitations, and low current densities (15). According to H-cells problems, the industries prefer continuous flow reactors which has potential to reduce CO₂. The continuous flow reactors: membrane reactor, micro-reactor, packed-bed reactor have various configurations design in order to overcome reaction limitations. Most of flow cell often design their stack by maximise its surface-to-volume ratio. However, maximising reactor surface-to-volume ratio necessitates many specialized parts and complicated assembly. Consequently, this project aims to develop a new type of electro-chemical reactor that is suitable for industrial-scale applications.

To optimize electrochemical reduction towards CO in flow cells, understanding how the operating parameter (e.g., temperature, pressure, cell potential, flow rate) impact on selectivity of CO production is essential. The novel electrochemical packed-bed reactor is designed for the electro-reduction of CO₂ to CO in the gas phase system. Furthermore, the effect of applied potentials and the influence of CO₂ flow rate were accounted to electrochemical packed-bed reactor performance.

1.2 Objective

1. To develop a novel electrochemical packed-bed reactor for CO₂ reduction in gas phase.
2. To study effects of applied voltages and flow rates on the CO₂ reduction performance.
3. To investigate the performance of a single-cell bed reactor compared to a two-cell bed reactor.

1.3 Scope of study

1. The performance of a single-cell bed and a two-cell bed reactor.
2. The applied voltages from 3 to 6 V for a single-cell bed and 8 to 11 V for a two-cell bed.
3. The flow rates of the CO₂ are 40, 80, and 120 ml min⁻¹.

Chapter 2

Theory and Literature reviews

2.1 Theory

2.1.1 Electroreduction of CO₂

Electrochemical reaction is the transformations of substance by shifting of electron. The electrochemical system generally consists of cathode and anode separated by an ion exchange membrane in electrolyte. The membrane acts as a charge carrier and barrier preventing mixing of other products crossing over. During this process, an external power source drives the electron transfer reaction, converting electrical energy to chemical energy of the reaction products. The electrochemical processes have several advantages (i) the reaction is adjustable by electrode potentials; (ii) the electrolytes can be recycled and minimized water consumption; (iii) the electric sources in process can be obtain from alternative energy sources; and (iv) the electrochemical process is easy to scale-up.

Figure 1 General electrochemical system feature.

In electrochemical carbon dioxide reaction, CO₂ is a linear stable molecule consisting of the oxygen atoms and the carbon atom. CO₂ reduction does not happen simply. Transferring an electron to CO₂ to generate CO₂⁻ is the rate determining step (RDS) that occur at -1.9V vs SHE because of the high energy barrier is more than the equilibrium value (17). The CO₂ reduction reaction pathway is difficult to control indicated in table 2 (18). Hori and colleagues have been working on CO₂ electroreduction in aqueous solution using different metal electrode and dividing metal electrodes into 4 groups in compliance with the main product (19, 20).

- (i) Pb, Hg, In, Sn, Cd, Tl, and Bi are selective for formic acid production.
- (ii) Au, Ag, Zn, Pd, and Ga produce CO as the major product.
- (iii) Cu electrode exhibits an outstanding electrocatalytic activity for multi-hydrocarbon products such as CH₄, C₂H₄ and alcohols, in which CO is formed as an intermediate.
- (iv) Ni, Fe, Pt, and Ti have low electrolytic activity to give production from CO₂ electroreduction, but hydrogen evolution occurs instead.

Nevertheless, the mechanism still needs to be understood further due to the complex synthesis through various type of the materials. In aqueous system, hydrolysis is comparatively positive to rate determining step. Accordingly, hydrogen evolution reaction (HER) favorably competes with CO₂ reduction, and H₂ is the main product (17). The major obstacle preventing conversion of CO₂ is the low solubility of CO₂ in aqueous solution. In addition, the product selectivity of this process can also be enhanced upon various factors, such as electrode potential, electrolyte solution, electrode material, applied voltage, and operating conditions (19,20). The integration of these factors is able to improve CO₂ reduction activities in the liquid phase reactor.

Table 2 Cathodic half-cell reactions in electrochemical CO₂ reduction at pH = 7. (18)

Cathodic half cell reaction	E ⁰ (V vs. NHE)
2H ⁺ + 2e ⁻ → H ₂	-0.42
CO ₂ + e ⁻ → *CO ₂ ⁻	-1.90
CO ₂ + 2H ⁺ + 2e ⁻ → CO + H ₂ O	-0.53
CO ₂ + 2H ⁺ + 2e ⁻ → HCOOH	-0.61
CO ₂ + 4H ⁺ + 4e ⁻ → HCHO + H ₂ O	-0.48
CO ₂ + 6H ⁺ + 6e ⁻ → CH ₃ OH + H ₂ O	-0.38
CO ₂ + 8H ⁺ + 8e ⁻ → CH ₄ + H ₂ O	-0.24

Despite attempts for increasing the CO₂ reduction performance, the feasible performance is still below the industrial demand. Electroreduction of CO₂ in the gas phase could minimise the drawback of aqueous electrolytes and recover desired product effectively. CO₂ gas flows toward to the cathode directly without liquidise leading to minimise operation cost (21). In addition, gas phase achieves a high current density and overcomes mass transport limitations (22). The key towards the electrochemical CO₂ reduction process is the optimization between the individual cell design and process efficiency.

Table 3 Faradaic efficiencies of the products in CO₂ reduction in 0.1-M TEAP in PC at various metal electrodes at -2.8 V vs. Ag/AgCl/(0.01 M LiCl + 0.1 M TEAP)/PC. quantity of the electric charge: 100. (20)

Electrode	Faradaic efficiency (%)					
	(COOH) ₂	OHCCOOH	HCOOH	CO	H ₂	Total
Pb	76.6	2.9	2.5	10.4	0.0	92.4
Cu	0.6	-	-	74.9	0.0	75.5
Ag	1.4	-	2.1	77.4	1.9	82.8
Au	0.2	-	3.7	83.2	13.9	100.9
Zn	0.4	-	-	89.7	0.0	90.1
Pt	1.0	-	7.7	66.6	17.4	92.7

2.1.2 Faradaic efficiency

Faradaic efficiency (FE) or current efficiency implies the selectivity toward a specific product. It is defined as the number of electrons utilized for the desired product formation over the total charge that passed through the cell. The formula for the current efficiency is

$$FE = \frac{ynF}{Q}$$

where y is the number of moles formed of the desired product, n is the number of electrons transferred in the half-cell reaction per mole of product, F is faradaic constant (96,485 C/mol electrons) and Q is the total charge passed between the electrodes (current*time).

2.1.3 Current density

Current density (j or CD) is the total current (I, in Amps) per unit area of the cathode (A/cm²) calculated by following equation. This parameter describes the reaction rate of a certain product under particular conditions. A greater current density indicates a higher reactant consumption rate.

$$J = \frac{I}{A}$$

Partial current density (j_{product}) for a specific product can be calculate by equation below which indicates a generation rate of the specific product.

$$J_{\text{product}} = FE_{\text{product}} \times J$$

2.1.4 CO₂ reduction to CO

The key for improving selectivity of electrochemical CO₂ reduction is CO₂ reactivity on the surface of a metal catalyst. Variety of transition metals have been studied on CO₂ electro reduction. The transition metals give different desire product either hydrogen, formic acid or carbon monoxide.

2.1.4.1 Gold (Au)

Gold (Au) is one of useful electrocatalysts for CO₂ reduction to CO. Hori et al. confirmed the CO production from CO₂ on Au electrode. The Tafel slope is around 130 mV decade⁻¹ in which indicated high partial current density on Au electrode (20). Later, Ikeda et al. investigated electroreduction of CO₂ on Au electrode in phosphate buffer solutions of pH 2 to 6.8. The Tafel slope is approximately 120 mV decade⁻¹ which agree with Hori's work. This indicates pH does not effect on CO formation at Au electrode, and H₂O act as proton donor not H⁺ (23). Eduardus et al. reported CO₂ conversion to CO using nanostructured gold catalysts. The CO faradaic efficiency increased to saturated point of 78% (-0.59 V vs. RHE) as the Au layer increased on carbon paper (24).

Figure 2 The CO₂ electroreduction performance of Au-T samples and Au foil: (a) CO faradaic efficiencies, (b) CO production rates and (c) total current densities of bare carbon paper, Au-T samples, and Au foil. (24).

2.1.4.2 Silver (Ag)

Silver (Ag) is known as high CO selectivity catalyst. The high CO selectivity of Ag catalysts is because the weak binding energy of both proton and CO on its surfaces, which inhibit HER and CO side reaction (25). The mechanism of CO₂ reduction to CO on silver surface is reported to be responsible via *COOH intermediate. The formation of *COOH possibly happens through a proton-coupled electron transfer (PCET) (R1), or a single electron transfer to form *COO⁻ (R2, R3) followed by protonation to give *COOH (R4) (26, 27). The schematic of CO₂ reduction to CO mechanism is shown in fig.3 (28).

Proton-coupled electron transfer

Single electron transfer

*CO and H₂O formation

The desorption of CO

Figure 3 A schematic depiction of proposed CO₂ reduction to CO reaction mechanism on thin film Ag catalyst (28)

Hatsukade et al. exhibited the results from the potential dependent activity and selectivity on silver surfaces. The outstanding faradaic efficiency of CO among other products, however, the overpotential regions are also affect selectivity of main products (fig 4.) (26). This reflects the kinetics and mechanism of CO₂ reduction reaction. Ma et al. shown result from oxide-derived silver (OD-Ag) for CO₂ reduction to CO. The overall CO production faradaic efficiency of oxide-derived Ag was prominently displaced toward the positive potential compared to untreated Ag. The electroreduction of CO₂ to CO of the OD-Ag was 80% faradaic efficiency at -0.6 V vs. RHE. Moreover, OD-Ag can create a local pH around OD-Ag surface which promote activity with significantly suppressed HER (29).

Figure 4 (a) Faradaic efficiency for each product as a function of potential, and (b) Tafel plot of the partial current density going to each product at different overpotential regions (26)

2.1.4.3 Zinc (Zn)

Zinc (Zn) is another metal which categorized as a CO or HCOO^- forming metal. Luo W. et al. synthesizes porous Zn electrocatalyst using facial electrodeposition for CO_2 electroreduction to CO as shown in fig.5. The electrocatalyst can convert CO_2 to CO with 95% of faradaic efficiency and 27 mA cm^{-2} at -0.95 V vs. RHE in 0.1 M KHCO_3 in H-type cell. While a flow cell reactor can reach 84% CO faradaic efficiency at -0.64 V and 200 mA cm^{-2} using Zn gas diffusion electrode (30).

(c) Comparison of CO production rate observed over P-Zn and other state-of-the-art nanostructured Zn catalysts. (d) Catalytic stability for P-Zn (30)

Rosen et al. synthesized nanostructured Zn dendrite electrocatalyst using an electrodeposition method for CO₂ conversion under ambient conditions. The Zn dendrite catalyst activity and CO faradaic efficiency are obviously higher than that compared to the bulk Zn catalyst in an aqueous bicarbonate electrolyte as shown in fig.6 (31).

The bulk symbols represent the CO faradaic efficiencies (31)

2.1.5 Electrolyte

Electrolyte plays important role in electrochemical reaction. The general properties should include good ionic conductivity, stable pH and absorption CO₂. Different type of electrolytes, concentration and pH affect to the product quality (32). The effect of pH in CO₂ reduction depends on electrolyte species (cation/anion) and its concentration. Bumroongsakulsawat et al. investigated the influence of pH on CO₂ reduction product selectivity in term of CO and HCOO⁻ ratio at Sn electrode. A change in ratio from 1 to 0.15 in pH 2.9 (0.1 M H₃PO₄/1 M NaH₂PO₄) to pH 7.8 (9.5 M NaOH) was observed. According to the results, decreasing pH enhanced the partial current densities of CO and HCOO⁻. Moreover, low pH was correlated with increasing in HER leading to decreasing in CO₂ reduction (33).

Figure 7 Meta-stable potential-pH diagram for C-H₂O system considering C^{IV}/C^{II} equilibria only at 298 K and 105 Pa. (33)

The selectivity and activity of CO₂ reduction relatively depend upon the local environment around the electrode such as pH value, CO₂ concentration, and electrolyte concentration. Nevertheless, the electrolyte is not the priority in the commercial process of CO₂ reduction as main targets regarding the performance. Yet, the separation and recycling of electrolyte still the issue to be manage, environment concern, and upscaling complexity.

2.1.6 Electrochemical cell for CO₂ reduction

The design of electrochemical cells is a critical step in CO₂ reduction, influencing cell performances such as current density, faradaic efficiency, and stability. Since Hori 's first revealed CO₂ reduction research in the 1980s, various cell designs have been investigation to improve CO₂ reduction reaction.

2.1.6.1 H-type cell

Fundamentally, H-type cell is lab-scale reactor for CO₂ Reduction, which widely used for gas and liquid products such as CO, and hydrocarbons. In this cell, both the working electrode and reference electrode are set in cathode chamber while the counter electrode is set in anode chamber. These electrodes are connected to external power supply and these two chambers are separated by ion-exchange membrane. Lu Q. et al. reported results from a nanoporous silver electrocatalyst in H-type cell. The CO selectivity approximately 92%. although this cell has feasibility on concept demonstration, but it still requires addition investigation for practical scale-up (34, 35).

Figure 8 PEM Cell Scheme of an alkaline MEA cell for electrochemical CO₂ reduction. (35)

2.1.6.2 Polymer electrolyte membrane (PEM) flow cell

This type of flow cell has potential to surmount the limitations of H-cell and it is a more promising technology for scale-up applications. Membrane electrode assembly (MEA) is deposition of catalysts on ion exchange membrane. PEM flow cells can be classified in three classes: cation-exchange membrane (CEM), anion exchange membrane (AEM) and bipolar membrane (BPM). A CEM has potential to transport cations from anode to cathode. In contrast, an AEM facilitates anions from cathode to anode. A BPM consists of cation and anion exchange membrane that water is dissociated to OH^- and H^+ , leading to constant pH, high current densities (36).

2.1.6.3 Microfluidic flow cell (MFC)

This electrolytic cell focuses on flowing of thin electrolyte channel between cathode and anode. The design of the flowing electrolyte is capable of tailoring operation conditions, including pH, and water management issues (37). Gabardo et al. reported a nearly 100% CO selectivity with the lowest overpotential 300mV at 300 mA cm^{-2} using an Ag-based GDE in microfluidic reactor as shown in fig.9. These improvements operated in a high alkaline condition and pressurized system (38).

Figure 9 Effect of pressure on CO_2 reduction at 300 mA cm^{-2} at various pressures and KOH concentrations on CO faradaic efficiency. (38)

2.1.6.4 Solid-oxide electrolysis cell (SOEC)

For CO₂ reduction at high temperature, a solid oxide electrolysis cell (SOEC) has been attracting due to its high efficiencies. The advantage of high temperature is promoting kinetics of reaction and reduces internal resistance Ye et al. have shown high performance CO₂ electrolysis with ca. 100% faradaic efficiency. The doped strontium titanate cooperated with Ni particle enables high temperature adsorption, activation and thermal stability with non-degradation after 10 redox cycles for 100 h (39). CO₂ electrolysis using a Ni/YSZ electrode supported solid oxide electrolysis cells (SOECs) was reported by Ebbesen et al. The passivation rate of the SOEC range was 0.22 to 0.44 mV h⁻¹ when reaction took place at current densities between -0.25 and -0.50 A cm⁻² in ratios of CO₂/CO = 70/30 or CO₂/CO = 98/02 at high temperature (40). However, SOEC has drawbacks due to its temperature operation, including carbon deposition, metal oxidation and cell degradation.

Figure 10 A Schematic diagram of solid-oxide electrolysis cell. (41)

2.2 Literature reviews

The complication of the CO₂RR pathway is difficult to achieve the CO product efficiently. Hence, it is significant to develop productive catalyst and technology for CO₂RR. Hori and co-worker convert CO₂ in 0.2 M K₂SO₄ solution using silver-coated ion exchange membrane electrodes (solid polymer electrolyte: SPE). The effect of membrane types (CEM and AEM) and SPE preparation were investigated. The Ag-coated SPE/AEM electrode CO₂ reduction result is remarkably over SPE/CEM electrode. They also compared the ultrasonic radiation and unmodified SPE/AEM. The ultrasonic electrode enhanced current density to 92% current efficiency at 20 mA cm⁻², in contrast, unmodified SPE reaches 74.4% current efficiency. The partial CO₂ current density is 60 mA cm⁻² that three times higher than upper limit of conventional electrode obtained compared to Ag electrode (42).

Figure 11 a) TEM image of Pt nanoparticles on the TPE-CMP surface; b) productivity for Pt doped CNT and TPE-CMP electrocatalysts (amount of metal: 10 wt. %, current: -20mA, T=60°C). (43)

As mentioned in early section, the utilisation of CO₂ in an aqueous solution brings mass transfer limitations that hinder scale-up. The continuous flow reactors: membrane reactor, micro-reactor, packed-bed reactor was developed configuration and design to maximise surface-to volume ratio. Electrocatalysts designed by Ampelli et al. for gas phase CO₂ reduction consist of conjugated microporous polymers (TPE-CMP) doped with Pt nanoparticles as shown in fig.11 and mixed with carbon nanotubes (CNT). The results indicated that an assembly of Pt metal, CMP and CNT is the key to improve proton mobility and electron conductivity. The electrocatalysts exhibited a good performance in terms of C1-C3 liquid product formation with at least 95% faradic efficiency (43). Jingjie Wu et al. converted CO₂ to formate in microstructure electrochemical cell as shown in fig.12 operated at a low current density (<30 mA cm⁻²). The results in fig.13 were reported in term of nafion loading, catalyst thickness layer and catalyst size particle. The Sn catalyst average particle size of 100 nm to 1.5 micrometer with 17-20 wt.%Nafion was found the highest in both current density and faradaic efficiency at -1.6V vs SCE. The effective catalyst thickness is 9 nm at -1.6V vs SCE with 20 wt.%Nafion and 100 nm of Sn (44).

The highly selective nickel nitride (Ni₃N) electrocatalyst was used for reducing CO₂ in both the aqueous phase and the gas phase compared to Ni and NiO that generated H₂. Hou reported 85.7% of CO faradaic efficiency was observed in aqueous solution with partial current density 6.3 mA cm⁻² at -0.90 V vs. RHE. When CO₂ flew through using the membrane-electrode assembly (MEA) consisted on anion-exchange membrane, current density reached 23.3 mA cm⁻² with the CO faradaic efficiency raised to 92.5% (45).

Gas diffusion electrodes (GDE), solid polymer electrolyte (SPE), and ion exchange membranes, where the catalysts are deposited directly on the membranes, are widely used for electrochemical CO₂ reduction. Wang et al. reported conversion of humidified CO₂ to CO on proton-exchange and alkaline anion-exchange membrane as shown in fig.15 using conventional Pt/C, Pd/C and Cu/CNTs as cathodic catalyst. Figure 16 shown a result from AAEM was successful in converting CO₂ to CO while PEM has no activity for CO₂ reduction. AAEM reactor also facilitates the CO₂ reduction reaction and prohibits the hydrogen evolution reaction (HER) at the cathode. Cu/CNT cathode catalysts shows a higher activity to convert CO₂ to CO among the other catalysts at the same catalyst loading (46). Kim studied the effect of dilute feed and pH on electrochemical reduction of CO₂ to CO in flow cell using Ag-GDE. The results confirmed even dilute CO₂ (10%) could be reached more 80% CO faradaic efficiency with 29 mA cm⁻² of CO current density at 3.0 V though current density is 55% less when operating with 100% CO₂ feed (47).

Yang et al. developed a novel three-compartment reactor for CO₂ reducing to formic acid. The reactor consists of a cation-exchange membrane and anion-exchange membrane. The cell produced formic acid operated at a current density of 140 mA cm⁻² with formic acid faradaic efficiencies of up to 94% at a cell voltage of 3.5 V (48).

Figure 17 The results from typical cell configuration in a single pass operation (a) current density, (b) Faradaic efficiency of formic acid. (48)

Delacourt and co-workers design electrochemical cell synthesis syngas from CO₂ and H₂O at ambient conditions. The effect of Ag GDE catalysts with and without a pH buffer layer (KHCO₃ aqueous solution) was studied. The results show that the pH buffer layer cooperated with the CEM system enhance CO selectivity to 80% and prohibited HER at -1.7 to -1.75 V vs SCE. While CEM configuration (fig.18a) suppressed CO₂ reduction reaction, leading to HER only. This pH buffer layer prevents excess amount of H⁺. Nevertheless, the presence of buffer layer in a modified CEM is not a suitable design for realistic application. To simplify a modified CEM, AEM configuration (fig.18c) was developed and obviously improved efficient of CO₂ reduction compared to CEM (49).

Figure 18 (a) Electrochemical cell with a cation-exchange membrane (CEM). (b) Modified electrochemical cell with a pH-buffer layer and the CEM. (c) Electrochemical cell with an anion exchange membrane (AEM). (d) Electrochemical cell based on a CEM in the K^+ -form. (49)

Verma et al. used a supported gold catalyst on polymer wrapped carbon nanotubes in an alkaline electrolyzer which provides high conductivity and high activate surface area. The electrolyzer exhibits high j_{CO} and overpotential at -0.55 V vs. RHE. The tefal slopes as shown in fig 19 indicates the rate limiting step for the CO_2 to CO is a pH independent. Thus, increasing pH of system can obtain high cell overpotentials (50). Dufek shown results from a pressurized electro-chemical cell for continuous CO_2 reduction at high pressure, using an Ag-based cathode. The quantity of produced CO at elevated pressure is 5 times higher than ambient pressure with 92% faradic efficiencies observed at 350 mA cm^{-2} . Their research also demonstrates benefits of increased temperature. At 225 mA cm^{-2} and 18.5 atm, Increased temperature from 60 to 90°C contributed to a cell voltage below 3V as shown in fig.19 equal to an electrical efficiency of 50%. (51).

Monroe et al. introduced a one-pass lamilar flow cell in fig.21 for electrochemical reduction of CO_2 to liquid fuel products. To be practical, a laminar flow in the separation strategy is significantly require partitioning the formate-containing electrolyte (0.1 M KHCO_3) produced and prevent oxidation products at Sn cathode surface at 5 mA cm^{-2} . The product trends of the experimental separation efficiency with channel width (W) and flow rates were corresponding to model predictions but the separation efficiency values are generally lower than model. (54)

Figure 21 (a) Cross section view of the Y-channel geometry of the laminar CO_2 reduction flow cell. CO_2 reduction flow separation efficiencies as a function of physical variables. (b) Flow rate varied at fixed $W = 5 \text{ mm}$ and channel width varied at $Q = 5 \text{ ml min}^{-1}$. (c) Overall faradaic efficiency and separation efficiency for formate production in laminar flow reactor. (54)

Hani reported the difference between a batch electrochemical cell and a flow cell for the electrochemical reduction of CO_2 using a porous gold cathode (55). The faradaic efficiency of CO in flow cell was 80-90% at any concentration, whereas in batch cell, the value dropped from 75% to 35% as the concentration is increased from 0.05 to 0.5 mol L^{-1} .

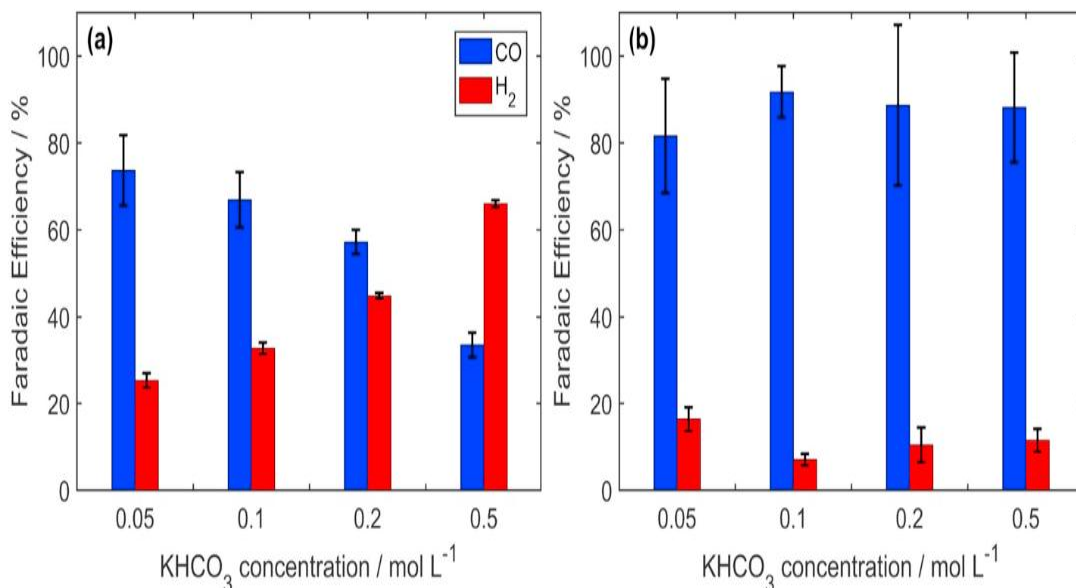

Figure 22 Faradaic efficiency for CO and H₂ (a) the batch cell; (b) the flow cell. (55)

Figure 23 Faradaic efficiency changes in the flow cell by time at: (a) -1.3 V; (b) -1.5 V using 0.2 mol L^{-1} KHCO₃ as the catholyte and a CO₂ bubbling flow rate of 20 mL min^{-1} . (55)

To be more similarly required industrial conditions, Dufek (56) investigated on the effect of the elevated temperature on CO₂ electrochemical reduction. Increasing the temperature above room temperature increased CO EF as shown in fig.24 to a maximum at 35°C but then decreases at 70°C. This indicated the decreasing in CO₂ solubility with temperature. For cell performance, at 70°C and 70 mA cm^{-2} E_{cell} drops by 1.57 V from 18°C to 70°C. The similar trend was observed in E_c decreased from -21.9 to -1.87 V for the same temperature. This indicates increasing in temperature minimize the process potentials needed. In case of effect of catholyte concentration and CO₂ flow rate toward syn-gas products (H₂:CO). The decreasing the CO₂ flow rate decreases amount of syn-gas produced as shown in fig.25.

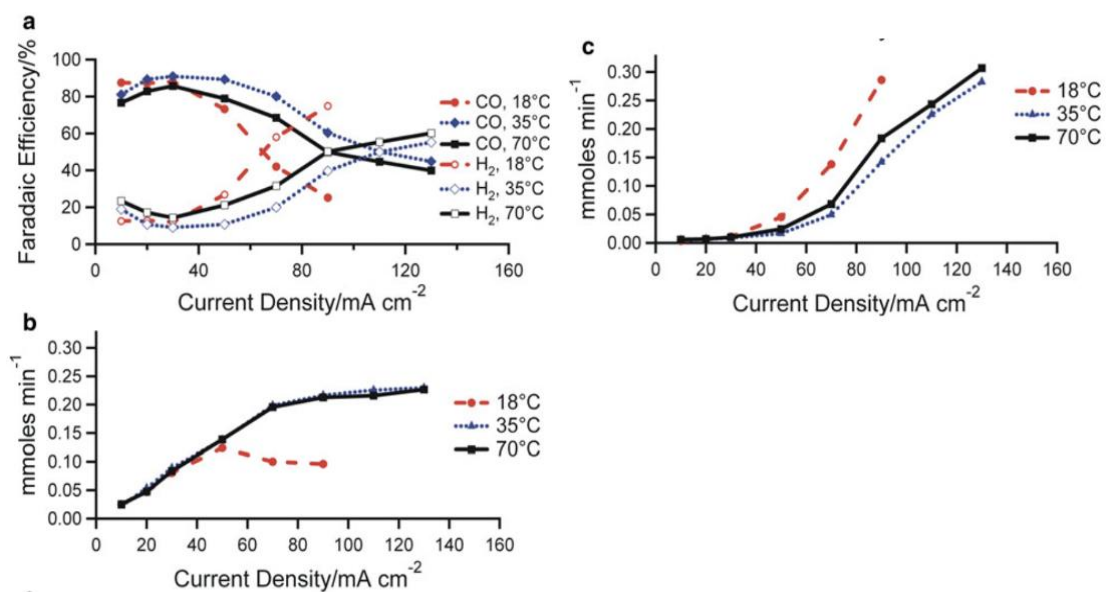

Figure 24 Cell performance at 18, 35, and 70 °C, CO₂ flow 20 mL min⁻¹ (a) FE for CO and H₂ (b) rate of produced CO, and (c) rate of produced H₂. (56)

Chapter 3 Methodology

3.1 Electrochemical cell

To achieve practical parameters for the electroreduction of CO₂, our cell design has been made to minimize complexity of cell components assembly. The novel electrochemical packed-bed reactor for CO₂ reduction in the gas phase is made from glass vessel that is shown in fig.26. The cell inside and outside diameter is 15 mm and 30 mm respectively with 6 mm of gas inlet. Titanium plates of 30 mm diameter are placed on the two ends to close to the cell chamber and are connected to a DC power supply. At the middle, electrocatalysts consisted of Zn-deposited felt, ion-exchange resin, and platinized titanium arranged in this order and fixed by the titanium mesh (Fuel Cell Store) connected with gold wire through the cell. EDPM (Fuel Cell Store) gaskets are inserted between the flange of the cell. C-clamps are used for holding the cell together. The cell was installed along the length of the reactor so that a gas stream could perpendicularly flow through all cell components.

Figure 26 The novel packed bed electrochemical reactor compartments.

3.2 Preparation of Zinc deposition

Zinc was deposited on carbon felt (Fuel cell store) with size about 1.76 cm² at 30 mA in aqueous solution of 1 M ZnSO₄ at pH4 adjusted by 1 M H₂SO₄ for 2 hours. The Titanium plate (Local supplier) and platinized titanium mesh (Fuel cell store) with a dimension of 2*5 cm² were used as support of carbon felt. Before deposition, carbon felt was pressed to remove air inside the pore. The Zn deposited carbon felt was rinsed with deionized water then drying at room temperature. The morphology of Zn plated carbon felt was characterized by Scanning electron microscopy (SEM).

3.3 Procedure

The 0.5 g of ion exchange resin (Dowex Marathon MSA chloride form, Sigma-Aldrich) was immersed into an aqueous solution of 1 M NaOH for 30 min then rinsed with DI water before packed into the electrolytic cell. The Zn plated carbon felt was used as cathode. CO₂ (Linde, 99.995 %) was continuously fed through a saturator before it was passed to the cathode side at flow rate of 40, 80, and 120 mL min⁻¹ controlled by a mass flow controller (MFC). The cell was always fed with CO₂ without applied voltage for 30 min to saturate the resin. For the experiments investigating the effect of the voltage, the voltage was adjusted from 3 (onset) to 6 V for 30 minutes. The voltage was then stopped for 5 min before starting the next batch to purge remaining gas products in the cell. An analogous set up was applied to a two-cell bed reactor with varying voltage between 8 to 11 V. CO concentrations were determined by an online IR spectrometer (Yokogawa, IR200-JNGHFGHKNN-4TU).

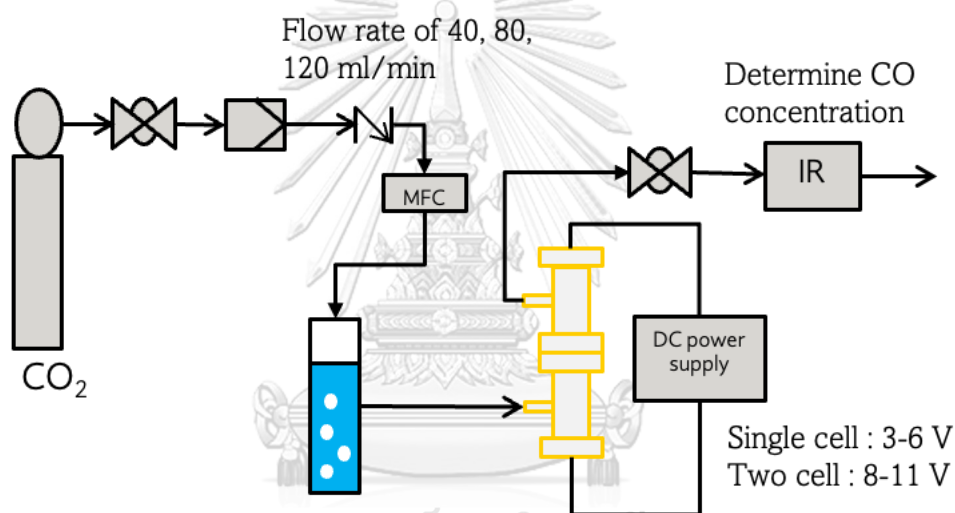

Figure 27 Process flow diagram of CO₂ reduction.

Chapter 4

Results and Discussion

The purpose of this work was to develop a novel electrochemical cell which could be scaled up. The applied voltage and flow rate were a focus because these parameters were required for industrial operation. Figure 28 shows a SEM image of zinc-carbon felt followed by the method described in Section 3.2. The zinc particles deposits appeared to cover the carbon fiber.

Figure 28 SEM analysis of (a) Carbon felt, and (b) Zn deposited carbon felt.

4.1 CO₂ reduction

4.1.1 Single-cell bed reactor.

Figure 29, 30 and 31 show the effect of applied potentials toward the electrochemical CO₂ reduction with Zn deposited felt. For single-cell bed reactor, the CO concentration was started forming at 4 V at any CO₂ flow rate. This evidence indicates that the minimum voltage for driving the reaction need at least 4 V for single-cell bed reactor. The current and CO concentration were corresponded with increased applied voltage. The CO concentration increased from 828 ppm for 40 ml min⁻¹ to 1825 ppm for 80 ml min⁻¹ at 6 V which increased CO Faradaic efficiency from 1.72% to 14.66%.

Figure 29 CO concentration (ppm) and current (mA) for CO₂ flow rate of 40 ml min⁻¹.

The plateau of current of ~5 mA and ~15 mA at 4 and 5 V respectively for all flow rates implies that the reaction becomes mass transfer limited under these conditions. Although the limiting current plateaus presents at flow rate of 80 and, 120 ml min⁻¹, the CO concentration monotonically escalate under applied voltages of 5 and 6 V. These results might be a consequence of a high flow rate indicated that the CO concentration partially depends upon mass transfer of CO₂ to the felt surface.

Figure 30 CO concentration (ppm) and current (mA) for CO₂ flow rate of 80 ml min⁻¹.

Figure 31 CO concentration (ppm) and current (mA) for CO₂ flow rate of 120 ml min⁻¹.

The sharply increasing of CO concentration at a high flow rate through porous cell could be describe by following scenarios: (1) The flowing CO₂ through packed-bed continuously removes CO from the felt pores releasing the CO from the catalyst surface, so that available active site for further CO₂ reduction. (2) The local pH in the felt pores is stable with fresh incoming CO₂. Thus, increasing in flow rate appears to be enhance mass transport of CO₂ reduction (57). Nevertheless, the effects of flow rate are need further investigations. The flow rate might against effects of enhancing mass transfer and due to short residence time at high flow rate. During the experiment of CO₂ reduction at 6 V with flow rate of 120 ml min⁻¹, water vapor was condensed in packed-bed leading to high current at this condition.

4.1.2 Two-cell bed reactor.

For two-cell bed reactor, both CO concentration and the current trends were consistency with increase applied voltage as shown in fig.32. The highest CO faradaic efficiency (12.43%) was observed at 11 V and 120 ml min⁻¹. This suggests that the optimum voltage for the CO selectivity is 11 V under the studied conditions. However, the effect of flow rate on CO₂ reduction in two-cell bed is inconclusive. The fluctuation of currents during the reduction was observed. The low currents compared to single-cell bed could be described by the deficiency of the water distribution. The water distribution within an electrochemical cell has impacted as a crucial factor in enhancing the CO₂ reduction performance. The presence of H₂O plays a significant role in improving the CO₂ reduction, such as increasing conductivity and proton donor (58) so that an unstable water distribution could lead to insufficient proton to complete the CO₂ reduction reaction.

Figure 32 CO concentration (ppm) and current (mA) for CO₂ flow rate of 40 (a, b), 80 (c, d), and 120 ml min⁻¹ (e, f) of a two-cell bed reactor.

Figure 33 Faradaic efficiency of (a) a single-cell bed and (b) a two-cell bed.

4.2 Cell stability

The results presented in fig.34 fast deactivate after 30 minutes of operation in packed-bed reactor. A felt was analyzed after use by scanning electron microscopy (SEM). After 30 min of operation, both the current and the CO concentration gradually declined. Fig.34b, the degradation of the used felt was observed and might cause the deteriorating performance (59, 60). The SEM images showed a flaking scattered on carbon fibre surface after CO₂ reduction. Further, the short-term operation in the packed-bed might be involve the water management. The cell stability for CO₂ reduction to CO was controlled by water delivery along the cell where dehydration of the electrochemical cell could reduce CO₂ reduction performance. Otherwise, the perspiration rate could also cause hampers the CO₂ diffusion. The accumulation of water in packed-bed of 120 ml min⁻¹ at 6 V (fig.30) was observed during the reaction so that accessibility of CO₂ to the felt active site was restricted (61). The excess water in packed-bed triggered water splitting which became main reaction instead of CO₂ reduction reaction caused unnecessary energy loss. Hence, the optimal humidify in CO₂ stream is one of the keys to maintain uniform current and electroreduction performance (62).

Besides, the bed porosity and thickness of packed-bed also suggest that mass transfer phenomena porosity between packed-bed might play a role in improved selectivity towards CO₂ electroreduction (63). The various patterns and designs including bed height, number of cell stack, and bed compact have impact on the diffusion of H₂O and CO₂ along the packed-bed. The nonuniform CO₂ and H₂O might contribute to fluctuation in current and CO concentration which complicated the cell performance analysis.

Figure 34 SEM analysis of (a) Zn deposited felt, and (b) a used Zn deposited carbon felt.

Chapter 5

Conclusions and Perspectives

Electrochemical packed-bed reactor for reducing CO₂ is being developed and was successfully converting CO₂ to CO. In this work, applied voltage and CO₂ flow rate was investigated on CO₂ reduction reaction in packed-bed reactor. An increasing in applied voltage increased the current and CO concentration for both single-cell configuration and two-cell configuration packed-bed reactor. Nevertheless, the effect of flowrates is still inconclusive. Increasing the flow rate might against effects of enhancing mass transfer because short residence time in the reactor. However, the two-cell bed reactor faced a water distribution problem, which decreased both the current and CO concentration. To modify the performance of our cell design, we have introduced several strategies for CO₂ reduction.

- Improvement the electrodeposition of Zn on carbon felt by adjusting the current.
- Solid porous polymer electrolyte membrane might be a clue for optimizing ion exchange, conductivity, and water transport.
- Varying time for NaOH absorption of the resin to efficiently capture CO₂.
- Optimized polymer loading to alleviate mass transfer limitation due to high compact of polymer.
- Controlling process parameters including humidity, flow rate, and pressure.

The investigations in this work are still at a primitive platform that require further commercial development and more variables need to be addressed which help to comprehend CO₂ electroreduction.

Appendix B

The faradaic efficiency in chapter 4 was calculated following the formula in section 2.1.2. Please note: Average current was substituted for this calculation, since current was observed nearly constant over time. The area of plot between CO concentration and time was obtained by Origin program.

Table 6 The area of graph CO concentration vs. time of 40, 80, and 120 ml min⁻¹ of a single-cell bed reactor.

Flow rate (ml min ⁻¹)	Average current (mA)				Area (ppm min)			
	3 V	4 V	5 V	6 V	3 V	4 V	5 V	6 V
40	0	4.83	12.5	27	0	1447.5	1870	2430
80	0	4	15.17	22.67	47.5	1130	7565	17360
120	0	5.17	13.67	46.33	155	52.5	6945	15265

Table 7 The area of graph CO concentration vs. time of 40-, 80-, and 120-ml min⁻¹ of a two-cell bed reactor.

Flow rate (ml min ⁻¹)	Average current (mA)				Area (ppm min)			
	8 V	9 V	10 V	11 V	8 V	9 V	10 V	11 V
40	9.33	10.67	10.67	8.5	565	1447.5	1555	692.5
80	5.83	8.17	8.67	6.67	470	620	555	375.5
120	9.33	12.83	13.83	8.5	1087.5	485	1665	1840

For example, calculate mole of CO at 6 V with CO₂ flow rate of 80 ml min⁻¹ of a single-cell bed reactor.

$$\text{Mole of CO} = \frac{17360 \text{ mol CO} \times \text{min}}{10^6 \text{ mol CO}_2} \times \frac{80 \text{ mL CO}_2}{\text{min}} \times \frac{1 \text{ L CO}_2}{1000 \text{ mL CO}_2} \times \frac{1 \text{ mol CO}_2}{22.4 \text{ L CO}_2} = 3.10 \times 10^{-5}$$

$$Q = 22.67 \times 10^{-3} \text{ A} \times 1800 \text{ s} = 40.80 \text{ A} \cdot \text{s}$$

$$FE = \frac{3.10 \times 10^{-5} \text{ mol} \times 2 \times \frac{96,485 \text{ A} \cdot \text{s}}{\text{mol}}}{40.8 \text{ A} \cdot \text{s}} \times 100\% = 14.66\%$$

Table 8 Faradaic efficiency of a single-cell bed reactor and a two-cell bed reactor.

Flow rate (ml min ⁻¹)	A single-cell bed reactor				A two-cell bed reactor			
	3 V	4 V	5 V	6 V	8 V	9 V	10 V	11 V
40	-	5.73	2.86	1.72	1.16	2.6	2.79	1.56
80	-	5.41	9.55	14.66	3.08	2.91	2.45	2.16
120	-	0.19	9.73	6.31	6.69	2.17	6.91	12.43
