6171934623 : MAJOR MARINE SCIENCE
KEYWORD: Chironex indrasaksajiae, box jellyfish, venom proteome, hemolytic assay, copper gluconate, heat

Chanikarn Yongstar : VENOM CHARACTERIZATION AND TOXICOLOGY OF BOX JELLYFISH *Chironex indrasaksajiae*. Advisor: Supanut Pairohakul, Ph.D. Co-advisor: Assoc. Prof. Thaithaworn Lirdwitayaprasit, Ph.D., Nuankanya Sathirapongsasuti, M.D., Ph.D.

Box jellyfish is considered one of the most venomous animals. The genus *Chironex* (*C. indrasaksajiae*) is a multi-tentacle box jellyfish found in Thai waters that are dangerous to humans, particularly the venom that could cause death within minutes. This study aimed to perform a proteomic approach to characterize the protein components of *C. indrasaksajiae* venom. A total of 532 unique protein groups were identified, including toxins and proteins essential for nematocyte development and nematocyst formation (nematogenesis). Toxins CfTX-1 and CfTX-2, with sequence coverage of 39.3 percent and 34.8 percent, respectively, are the most abundant in the venom of *C. indrasaksajiae*. The CfTX-like proteins are members of a group of potent toxins unique to Cnidaria. These toxins are linked with cytolytic, hemolytic, inflammatory, dermonecrotic, and deadly activities. This work is the first to describe the cubozoan jellyfish venom proteome and sheds light on the range and diversity of protein toxins produced by this dangerous box jellyfish. Furthermore, our findings indicated that the venom had strong hemolytic activity that demonstrated 100-fold more potently hemolytic activity (HU_{50}) than *C. fleckeri* which is currently mentioned as the most lethal animal on the planet. Current therapies focus on symptom alleviation after envenomation. Therefore, effective treatments are required to lower the death rates associated with cnidarian envenomation. Copper gluconate showed the potent inhibitory effect on the hemolysis induced by *C. indrasaksajiae* venom. The considerable inhibition of hemolytic activity following cubozoan stinging by copper gluconate-based products represents a novel and effective therapeutic approach for the treatment of cnidarian envenomation. Heat also influenced the hemolytic activity induced by *C. indrasaksajiae* venom. At 37°C and 45 °C, the temperatures appropriate for such inactivation of the venom activity. This work provides an enhanced understanding of *C. indrasaksajiae* box jellyfish venom that can be used for future comparative studies, toxin evolution analysis, and drug discovery.

ACKNOWLEDGEMENTS

I would like to thank all my advisors involved in this thesis at different stages; Dr. Supanut Pairohakul, Dr. Nuankanya Sathirapongsasuti and Assoc. Prof. Thaithaworn Lirdwitayaprasit, my endless gratitude for your guidance, patience, and dedication to helping me grow both academically and personally. Thanks for mentoring me throughout all the highs and lows and for sharing your enthusiasm, knowledge, and professionalism during these four years. I especially thank Dr. Nuankanya Sathirapongsasuti, I'm very grateful to you for opening the doors of your laboratory to me. Without your support, this project would not have been possible.

I am also grateful to my committee members, Asst. Prof. Kornrawee Aiemsomboon, Asst. Prof. Jes Kettratad, and Asst. Prof. Udomsak Darumas, for their ongoing mentoring and support of my development as an independent scientist.

A special thanks to Dr. Waeowalee Choksawangkarn and Napassawan Panya for contributing with your great expertise in the proteomics and bioinformatics fields, for supporting my project during all these years, and for receiving me in your lab at Burapha University, where I spent a really great time. Thanks for all the chances you've given me and for telling me about your experiences, which will help me a lot in the future.

A big thank you to lab member, Kasetsin Khonchom, at Ramathibodi for your help in my laboratory process and field trip for box jellyfish collections.

Big thanks to all my friends from the marine science department, for giving me the opportunity to share a great time with you and for organizing amazing events. To my best friends, Juthamas Phothakwanpracha and Chaleonlak Suchartpong, thanks for your positive words, your friendship, love and support, for being such great company during my stay at the Department, and for bringing joy, music, and yummy food to my life during these tough years:).

Thanks to my family for always being present in spite of the distance and for your immense support. In particular, all my love goes to my parents, who are my biggest heroes.

Thanks to Chulalongkorn University and the Thai government (Development and Promotion of Science and Technology Talents Project Scholarship) for supporting and funding my thesis, paying my tuition, and giving me a monthly stipend for the past 4 years.

CHAPTER I
Introduction

1. Research background and rationale

In recent years, the incidences of marine envenomation appear to be increasing worldwide due to global warming and the rising frequency of human encounters with venomous marine creatures (Needleman et al., 2018; 2018). Many humans experience jellyfish stings, particularly along with coastal areas of the ocean where numbered millions of stings occur annually (Fenner, 1997a). By stinging, many jellyfish species have been known to cause injuries or even death (Cegolon et al., 2013; Fenner and Williamson, 1996; Mubarak et al., 2021; Tibballs, 2006b). Such serious reactions which can be more than 100 fatal cases per year (Pirkle and Yanagihara, 2019), are consequences of stings inflicted by Australian box jellyfish *Chironex fleckeri*. This species is considered as one of the most venomous marine creatures in the world (Williamson et al., 1996). A meter of tentacle contact can occasionally result in death attributed to acute cardiovascular collapse within minutes after stinging (Yanagihara and Shohet, 2012).

Thailand locates in the Indo-pacific region, where it is the hotspot zone for box jellyfish envenomation (Gershwin et al., 2010; Gershwin et al., 2013) (Figure 1). The medical records showed the envenomation cases of box jellyfish (both Thai and foreigners) in Thai water since 1998 (Thaikruea and Siriarayapon, 2014). However, many people do not believe that box jellyfish can kill humans, so they dismiss and neglect this problem. Thus, the knowledge about box jellyfish biodiversity or envenomation has been limited in Thailand. Until now, there have been six fatal cases of box jellyfish envenomation occurring on the islands of Samui and Pha-ngan in the Gulf of Thailand (Thaikruea and Siriarayapon, 2016). All these fatal cases may be caused by *Chironex indrasaksajiae* which has recently been described as a new species of box jellyfish from the Gulf of Thailand (Sucharitakul et al., 2017). *C. indrasaksajiae* envenomations occur each year, typically from August to November (Thaikruea and Siriarayapon, 2016).

Numerous biological activities are related to cubozoan venoms. Particularly, *Chironex* sp. entire tentacle and nematocyst extracts produce lethal, dermonecrotic, nociceptive, cytotoxic, neurotoxic, myotoxic, cardiotoxic, and hemolytic effects (Tibballs, 2006b). Nevertheless, despite the clinical and pharmacological relevance of box jellyfish venoms to humans, their compositions have not been thoroughly studied. This thesis described the proteomic characterization of *C. indrasaksajiae* venom to identify proteins that may contribute to the deleterious effects of box jellyfish stings in humans. To date some known components in toxins, including porin, proteases, lipases, small molecular weight compounds, and lipids have been formally identified. Of these, a porin or a pore-forming protein is the fast-acting component in the venom. This protein can create pores on the membrane of human red blood cells, making them leak, release large amounts of potassium, and may cause cardiac arrest and death (Yanagihara and Shohet, 2012). Therefore, this study focused on porins activities. Copper gluconate and heat were also tested in the study because these two factors have been reported that the treatments can perturb the self-assembly of porins (Avigad and Bernheimer, 1976; Melo et al., 2016; Yanagihara, 2019). This therapy is limited and transient to support cardiovascular hemodynamics. It may allow for more effective treatment.

2. Objectives

1.2.1 Characterization of the proteins in *C. indrasaksajiae* venom

1.2.2 Effect of the venom from *C. indrasaksajiae* on sheep RBCs

1.2.3 Effect of copper gluconate and heat on the activity of venom

3. Expected beneficial outcomes

The results of this study will clear up the details of biochemical components in *Chironex indrasaksajiae* venom together with mechanistic and kinetic studies of the venom on human red blood cells using the hemolytic assay. Moreover**,** this study will provide important insights to suggest primary therapeutic approaches.

CHAPTER II
Literature review

1. Introduction

Marine venomous creatures have been identified in various phyla throughout the animal kingdom, such as Cnidaria, Platyhelminthes, Nematoda, Mollusca, and Echinodermata (Williamson et al., 1996). Among the members of these divisions, the Phylum Cnidaria is the most abundant and diverse group comprising more than 10,000 living species (Zhang, 2011, p. 9). Cnidarians appear to have diverse morphologies, including five main classes: Hydrozoa (hydroids, hydras, siphonophores), Anthozoa (hard and soft corals, sea anemones), Scyphozoa (true jellyfish), Cubozoa (box jellyfish), and Staurozoa (stalked jellyfish) (Figure 2), but all members of this phylum universally possess stinging capsules, known as nematocysts or cnidae, which give the phylum its name. These stinging organelles produce specialized toxic secretory products for capturing prey. However, the nematocysts of some groups are highly dangerous. More than 100 species are toxic to humans, and contact with these toxins causes a wide range of conditions, from cutaneous rashes to cardiovascular and respiratory collapse (Fernandez et al., 2011). The most dangerous group is the Cubozoa, commonly called "box jellyfish." Although Cubozoa is the smallest class of Cnidaria, comprising some 50 described box jellyfish species (Bentlage, 2012), they comprise the most highly specialized class of the Cnidaria phylum. They account for the majority of deaths among jellyfish-stung victims worldwide (Fenner and Williamson, 1996).

1.1 General characteristics of box jellyfish

Box jellyfish is the common name for the members of the class Cubozoa. One of its distinctive characteristics is the cubic shape of their bells, as opposed to crowns or dome-shaped bodies (Bentlage et al., 2010). It is for this reason that they are known as “Box Jellyfish.” (Brinkman and Burnell, 2008) Some species can have up to 15 tentacles growing from the corners of the cube-shaped bell, and all

jellies share the same origin of attachment sites. These tentacles can be up to 10 feet in length and hold up to 5,000 stinging cells per cm^2 (Hartwick, 1991b; Williamson et al., 1996). The venom contained in nematocysts is among the deadliest in the world. Box Jellyfish venom contains toxins that could attack the heart, skin cells, and nervous system (Brinkman and Burnell, 2008; Carrette and Seymour, 2006; Jouiaei, Yanagihara, et al., 2015; Winkel et al., 2005). Patients stung by box jellyfish could go into shock and experience heart failure, resulting in death within minutes (Ramasamy et al., 2004; Sharmaine Ramasamy et al., 2005; S. Ramasamy et al., 2005a, 2005b, 2005c). Members of the box jellyfish have clusters of eyes on each of the four sides of the jellyfish's bell. They can produce images with the refractive index gradient of their lenses. It aids them in locating prey and avoiding predators (Nilsson et al., 2005). Besides, box jellies can also swim vigorously. For example, *Chironex fleckeri* can swim at a rate of about 4 knots, whereas most jellyfish can only keep themselves in the current and merely drift with the current. As a result of these features, the box jellyfish is able to hunt prey while avoiding predators (Hamner et al., 1995; Shorten et al., 2005). Last but not least, box jellyfish has transparent-blue bodies. As a result, distinguishing between them underwater is extremely difficult, resulting in human damage (Cegolon et al., 2013; Suntrarachun et al., 2001).

Box jellyfish are classified into two distinct orders based on the number of tentacles that arise from each corner: order Chirodropida and order Carybdeida

1.1.1 Order Chirodropida (multiple tentacles group)

They are distinguishable from other box jellyfish by the presence of branching muscular bases at the corners of their cubic umbrellas and small saccules linked with the stomach cavity. They generally have multiple tentacles at each corner. Each year, members of this group kill a large number of people, typically in the tropical Indo-Pacific area. Approximately 7 chirodropid genus worldwide have fast-acting venom (Fenner et al., 2010). The most well-known genus *Chironex*, sometimes known as "sea wasps," is infamous for its capacity to cause lethal stings or severe systemic symptoms (Endean et al., 1991; Fenner, 2005; Fenner and Williamson, 1996; Learmont, 2006; Lippmann et al., 2011).

1.1.2 Order Carybdeida (single tentacle group)

They have unforked pedalia, with only one tentacle attaching to each corner of the bell. They range in size from a few millimetres to 500 mm in bell height. A large number of the species in order Carybdeida may cause the Irukandji syndrome. The main genus is *Alatina, Carukia, Malo,* and *Morbakka*. The consequences and symptoms of envenomation are quite delayed, appearing 25-40 minutes after being stung by a jellyfish (Carrette et al., 2012; Gershwin et al., 2013).

1.2 The genus *Chironex*: taxonomy and distribution

Although the box jellyfish has been considered as "the world's most venomous creature", it has been reported that only a few species in the class are involved in human deaths, specifically members of the genus *Chironex*. From the latest revision of the phylogeny of the genus *Chironex,* there are currently three recognized species of the genus *Chironex* in the world (WoRMS database: Collins and Jarms, 2021). First is *Chironex fleckeri* Southcott, 1956 (Figure 3a). This species is the largest species of cubozoa, with an averaging bell height of about 25 cm (almost the same size as a basketball ball) when mature (Kingsford and Mooney, 2014). It caused fatalities (at least 68 deaths since the first report in 1883) in Australia (Fenner, 2005; Lumley et al., 1988; Williamson et al., 1996). Second, *Chironex yamaguchii* Lewis & Bentlage, 2009, commonly known as habu-kurage (Figure 3b). This species caused several deaths (at least-three confirmed deaths) in Japanese waters (Lewis and Bentlage, 2009). The last one, *C. indrasaksajiae* , Sucharitakul, 2017, a new species of box jellyfish from the Gulf of Thailand, has killed six people since 1998 (Sucharitakul et al., 2017; Thaikruea and Siriarayapon, 2014) (Figure 3c).

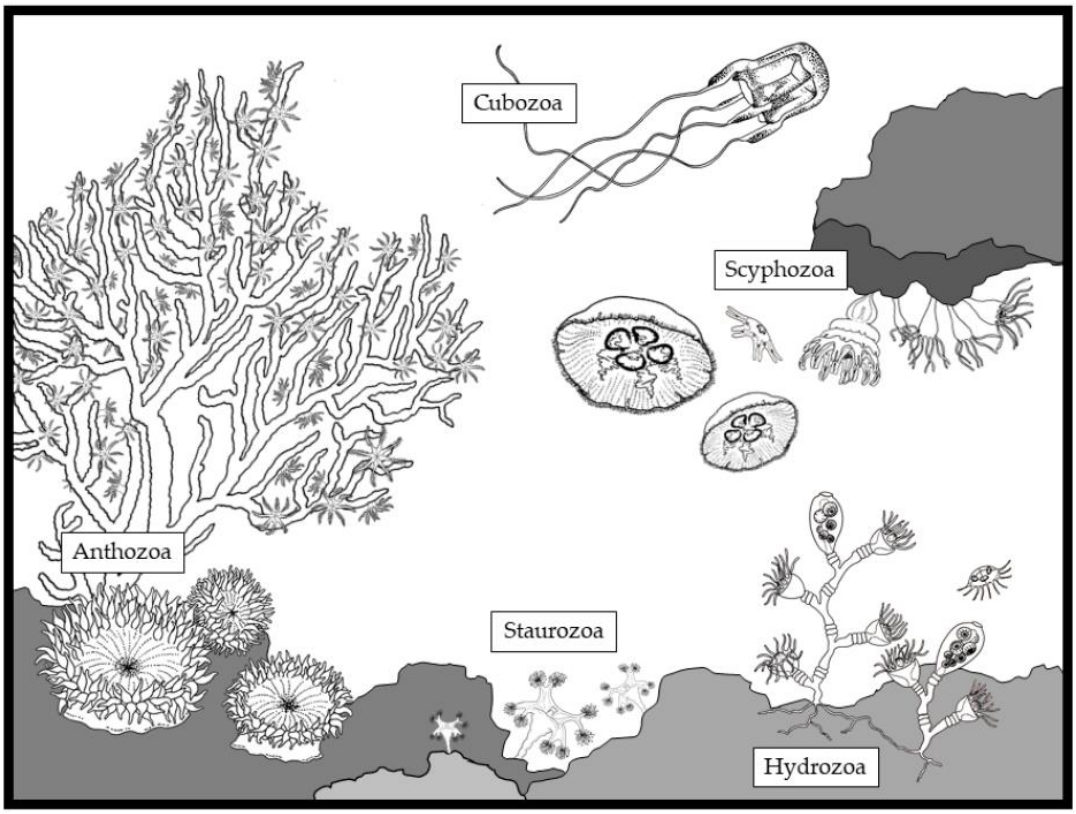

Figure 2 The diverse organisms belonging to the phylum Cnidaria within the main classes: Hydrozoa (hydroids, hydras, siphonophores), Anthozoa (hard and soft corals, sea anemones), Scyphozoa (true jellyfish), Cubozoa (box jellyfish), and Staurozoa (stalked jellyfish). Source : D'Ambra and Lauritano (2020)

1.3 The genus *Chironex*: life cycle

During the mating season, sea wasps have a natural tendency to aggregate in a coastal, estuary, or enclosed waters to produce their offspring, increasing the danger of unavoidable stinging to swimmers or fisherman, which many negative impacts on tourism and fishery, and among other human activities. *Chironex* has a polymorphic life history in which it may reproduce sexually with gametic meiosis as well as asexually, or without sex, like the other class members. To begin, the mature jellyfish swims to a nearby freshwater river (estuarine) in quest of a suitable mating. According to Hartwick (1991), the estuaries and exposed coastline provide suitable environmental conditions for polyps and medusae. Cubomedusae that have reached maturity release their gametes into the water column, where they are fertilized and grow into planula larvae. After spawning, they die and do not participate in raising their descendants. Planulae spend a few days swimming in the water column before settling on the substrate. After settlement, the planulae grow into polyps. The polyp stage is a tiny, sessile predator that ambushes prey. While they are developing, these polyps' major food sources are zooplankton and phytoplankton. This stage undergoes asexual budding to take immediate advantage of local increases in the food supply. The minimal requirements of the medusae stage include a stable hard substrate for attachment that allows it to maintain its population until the environment favors the survival of the medusa. The polyps are developed after a few months of feeding. The polyps then transform into a single juvenile medusa. Afterwards, juvenile medusas grow up into adult medusae form. (Gordon and Seymour, 2012; Hartwick, 1991a; Kingsford and Mooney, 2014). A summary of cubozoa life history is provided in Figure 4.

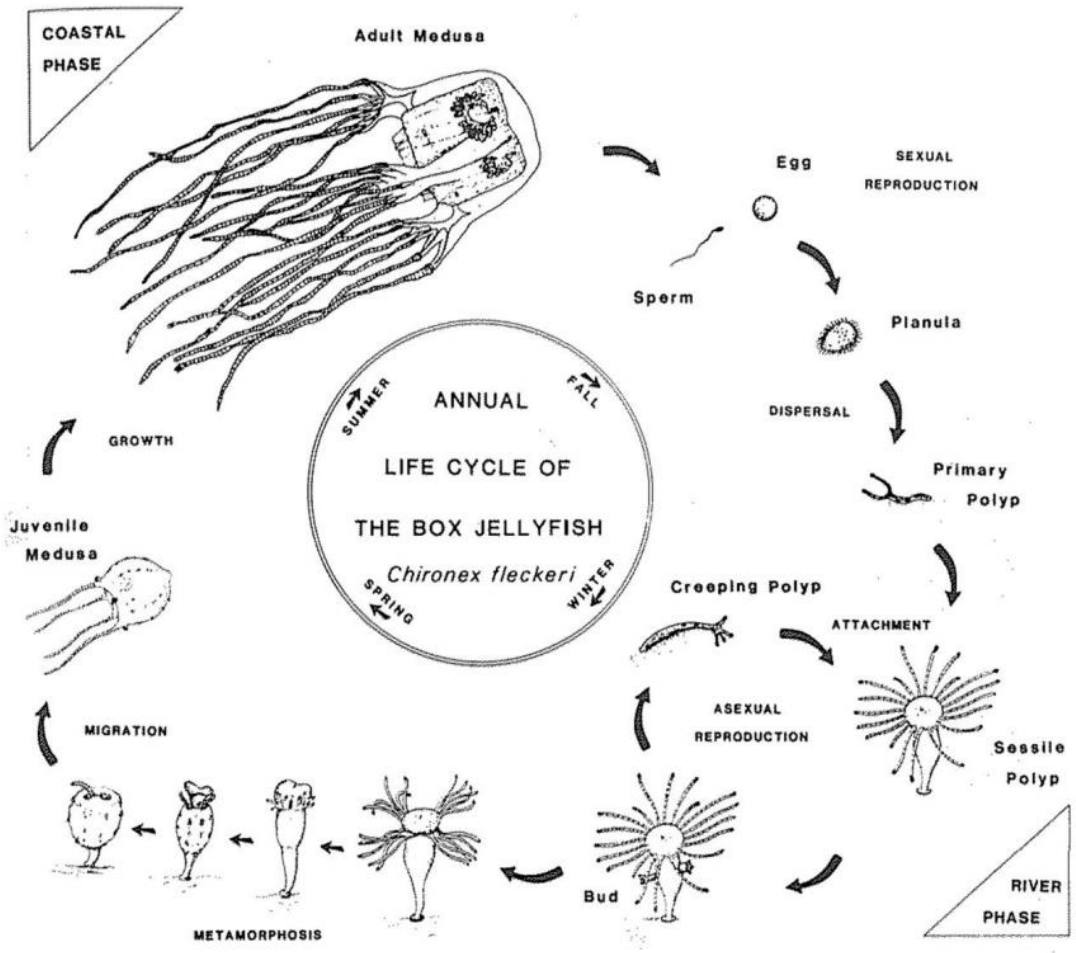

Figure 4 The *Chironex fleckeri* life cycle shows an alternation in both generations (sexual medusa phase to asexual polyp phase) as well as between the estuarine and coastal habitats Source : Gordon (2014))

1.4 The genus *Chironex*: anatomy

In general, the medusa form of this genus has a cubic shape or box-shape bell (figure 5). From each of the four lower corners of the bell hangs a short stalk called claw-like shaped pedalium that bears multiple long, slender tentacles. There are no nematocyst warts on the outer surfaces of the bell. Nematocysts are usually only found on their tentacles. The margin of the bell is folded inwards to form a shelf. It is called "velarium," which restricts the bell's cavity and creates a powerful movement when the bell pulsates (Schierwater and DeSalle, 2021, p. 161). As a result, the ability to locomote box jellyfish is more rapid than that of other jellyfish. The speeds that have been recorded can be up to six meters per minute (Shorten et al., 2005). At the centre of the bell is a mobile appendage called the "manubrium," which looks like an elephant's trunk. The tip of the manubrium is the mouth. The gastrovascular cavity that is known as the interior of the bell is divided by four septa into a central stomach and four gastric saccules with V-shaped gastric phacellae. The shape of the gastric saccules is the key characteristic of this genus. The distinctive gastric saccules of *Chironex* members have been described as cock's comb-like or grape cluster-like (Gershwin, 2005b; Lewis and Bentlage, 2009).

The nervous system of box jellyfish is more developed than other jellyfish. They have a nerve ring around the base of the bell that can control coordinates their pulsing movements. Box jellyfish are unique in the property of true complete eyes. There are retinas, corneas, and lenses. Their eyes, known as "rhopalia," are clusters of six eyes located in pockets called "dome-shaped rhopalial niche ostia in each half of the bell's outer surfaces" (Lewis and Bentlage, 2009; Ruppert et al., 2004; Southcott, 1956). Box jellyfish contains a total of twenty-four eyes, including twenty ocelli (simple eyes). Instead of just differentiating between light and dark, the jellyfish can detect specific spots of light and can produce images with the refractive index gradient of their lenses. Statoliths beneath the rhopalia sense gravity pull and facilitate the jellyfish in orienting itself (Nilsson et al., 2005; Ueno et al., 1995).

A fully grown *Chironex* can measure up to 20 cm along each box side (or 30 cm in diameter) (Kingsford and Mooney, 2014), and the tentacles can grow up

to 3 m in length. Its weight can reach 2 kg. There are about 15 tentacles on each corner ((Hartwick, 1991b; Tibballs, 2006b). Each tentacle contains bands or buttons of thousands of densely packed nematocysts that line the epithelial surfaces of tentacles that can inject venom into the victim (Rifkin and Endean, 1983; Williamson et al., 1996). This is a deadly organ that can cause serious damage, and many different types of nematocysts are found in this species (Gershwin, 2006).

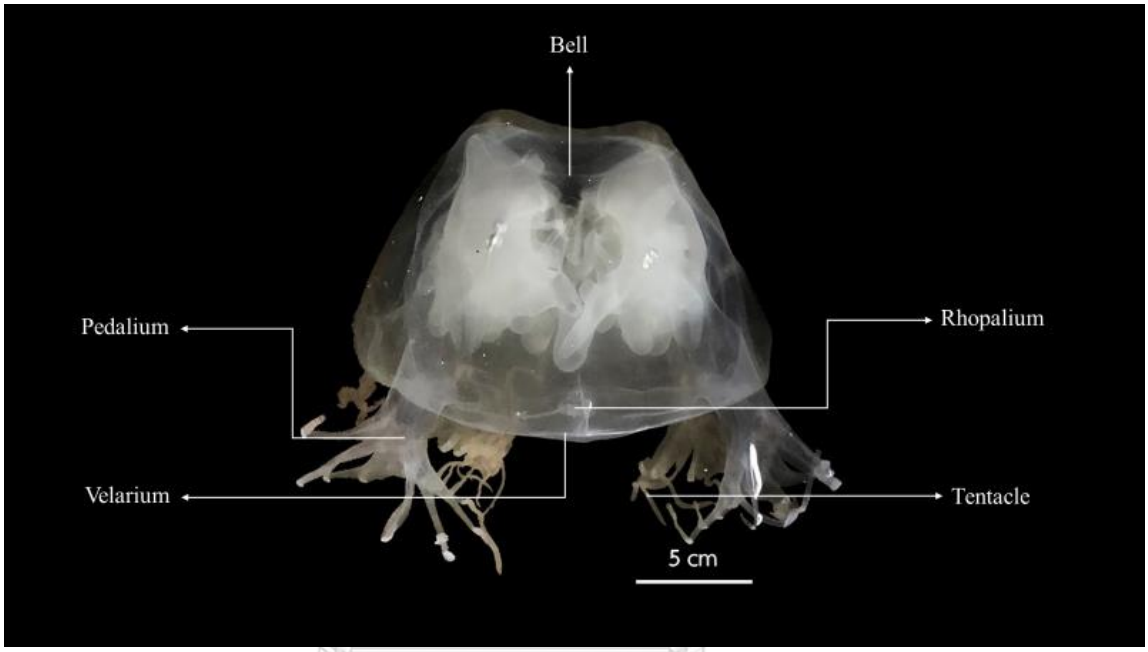

Figure 5 Morphology of a box jellyfish (*Chironex* sp.) (Photographs by Chanikarn Yongstar)

2. Cnidae

Cnidocyte is a unique and distinguishing feature of all Cnidarians. It is a remarkable, specialized, explosive organelle formed in a giant post-Golgi vesicle by a sequential accumulation of proteins from the Golgi apparatus. It comprises a collagen-walled capsule that undergoes further structural modifications in the extracellular matrix before migration to the tentacle surface (Beckmann and Özbek, 2012a; Jouiaei, 2016; Özbek et al., 2009). Each cnidocyte holds “a cnida” filled with fluid and contains a long tubular invagination of the capsule wall. Depending on the type of cnidae, the everted tubule may sting or paralyze prey by penetrating the epidermis and

releasing toxins, sticks to the prey's or substrate's surface, or fulfilling other functions. (Peach and Pitt, 2005).

Cnidae have been classified into three main types: penetrant nematocysts, the volvent spirocyst (Mariscal, McLean, et al., 1977) and the glutinant ptychocysts (Mariscal, Conklin, et al., 1977). In cubozoa, nematocysts are the only type of cnidae that comprise the cnidome, and three main categories of nematocysts are commonly found: mastigophore, euryteles, and isorhizas (Gershwin, 2006; Jouiaei, 2016; Östman, 2000). The study of cnidomes, and also information upon morphology of cnidae, are now regarded as an important part of jellyfish species identification (Acuna et al., 2003; Conklin et al., 1977; Östman, 1982; Ryland et al., 2004). Additionally, the function of each type of nematocyst has been described based on the structure (Rifkin and Endean, 1983). Consequently, the toxin should differ amongst nematocyst types (Carrette et al., 2002). Subsequently, the nematocyst ratio variation could reveal each species' venom level (Killi et al., 2020).

For Chirodropids, cnidae occur only in the gastrodermis or epidermis of jellyfish tentacle. The mature nematocyst capsule contains (1) a rapidly eversible penetrate of the non-penetrate tubule, (2) a complex mixture of proteins (often proteins), and (3) other small molecular weight compounds (Özbek et al., 2009; Yanagihara, Kuroiwa, Oliver, Chung, et al., 2002; Yanagihara, Kuroiwa, Oliver, and Kunkel, 2002).

Upon the nematocyst discharged, the initiation of the exocytosis process is stimulation of the cnidocilia (a hair-like trigger) on the outer surface of the nematocysts (Figure 6). The discharge process is one of the fastest events known in the animal kingdom. It can expel a tubule 200–800 microns in length at speed up to 18.6 m/s with an acceleration of more than 5,000,000 g and create pressure up to 7.7 GPa at the site of impact, allowing the tubule to penetrate human skin and a thick-cuticle of a prey crustacean (Beckmann and Özbek, 2012a; Nüchter et al., 2006; Özbek et al., 2009; Tardent, 1995).

Upon contact with human skin, thousands of tubules then evert themselves and drive through the skin within milliseconds. The first part of the tube has a set of spines that lock into the epidermis, providing the tube with a stable base, followed by the rest of the tubule extending into the dermis. The venom inside the cell is promptly

passed down via the tube and deposited in the dermis. The length of the penetrant tubules renders possibly the direct deposition of toxin into pierced capillaries, thus explaining the rapid onset of toxicity in humans (Figure 7) (Law, 2018; Rifkin and Endean, 1983; Tibballs, 2006b; Tibballs et al., 2011).

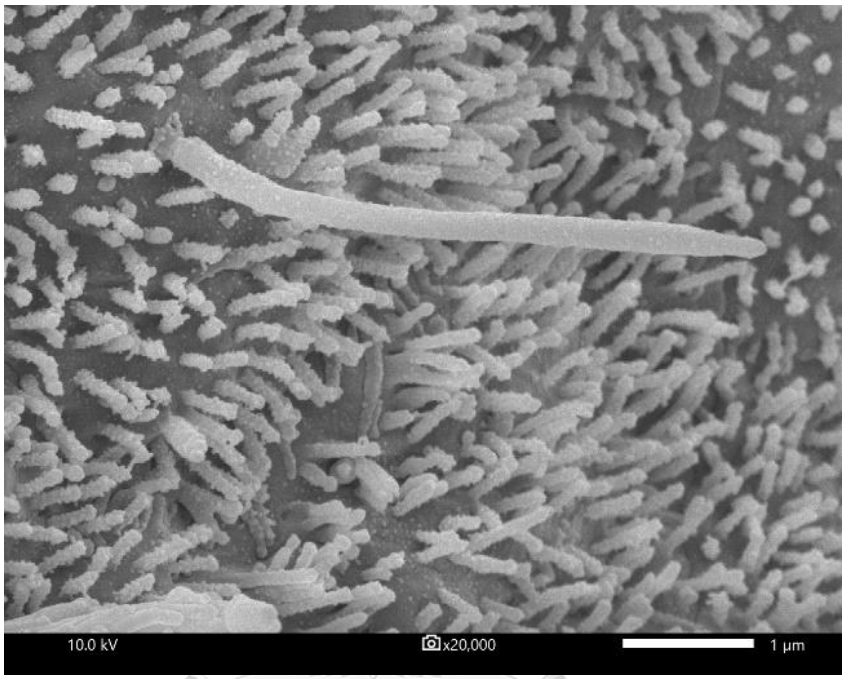

Figure 6 The sensory cilium of the nematocysts is mechanoreceptive may be, non-motile and stiff and is called Cnidocilia. (Photographs by Chanikarn Yongstar)

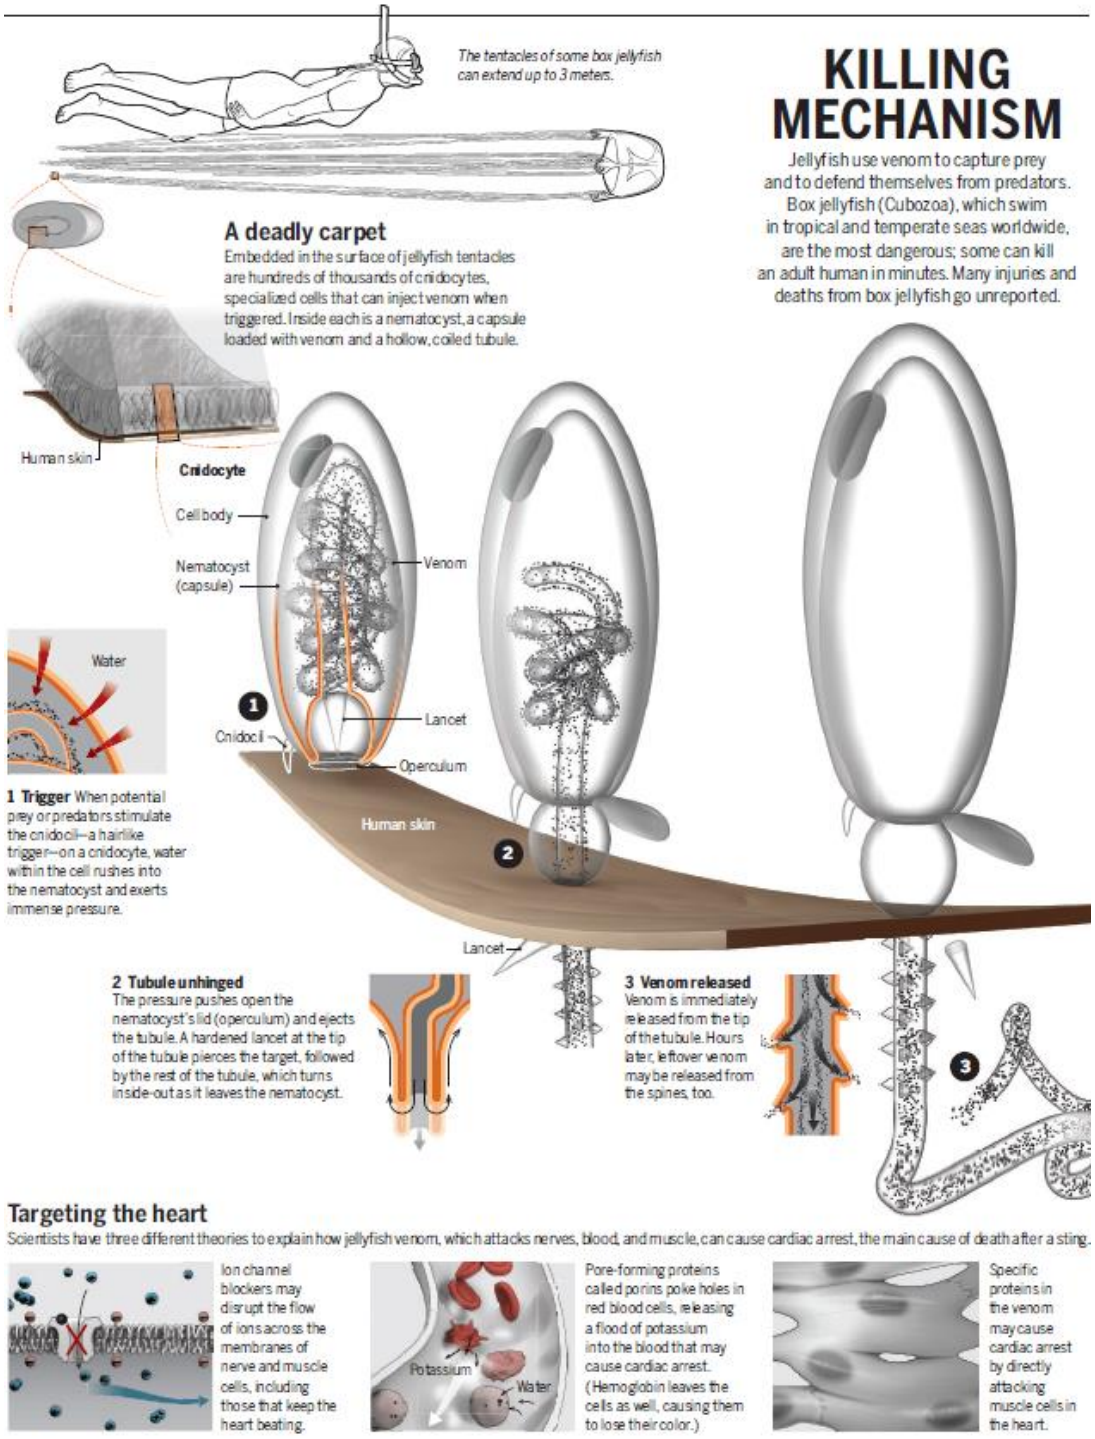

Figure 7 Killing mechanism of a box jellyfish (*Chironex* sp.) Source : Law (2018)

3. Box jellyfish in Thai waters

Box jellyfish are found mostly in tropical latitudes. They are especially abundant in the Indo-Pacific area, which is regarded as a hotspot zone for box jellyfish envenomation (Gershwin et al., 2013). Every year, thousands of severe stings and potentially hundreds of fatal envenomations were reported (Fenner, 1997b). Occasions of these cases were commonly reported in Northern Australia, and others were reported from tropical regions such as the Philippines, Borneo, Japan, Malaysia, and Thailand. (Fenner, 2005; Fenner et al., 2010; Fenner and Williamson, 1996; Fernandez et al., 2011; N.-S. Lee et al., 2001; Lippmann et al., 2011; Pirkle and Yanagihara, 2019; Suntrarachun et al., 2001; Thaikruea and Siriarayapon, 2018; Thaikruea et al., 2012b; Tibballs, 2006b; Tiemensma et al., 2021; Vimpani and Harris, 1988; Williamson et al., 1980)

After the Ministry of Public Health (MOPH) reported the first suspected box jellyfish envenomation in Thailand, when two foreign tourists died on Pha-Ngan Island, Surat Thani province. The investigation discovered clinical symptoms compatible with envenomation by multi-tentacled box jellyfish. At the time, no government authorities in Thailand had heard of box jellyfish murdering people. There was a strong belief that the fatalities were caused by Caucasian people's hypersensitivity to local jellyfish toxins. After a Swedish girl died at a beach on Lanta Island in 2008 with anaphylactic shock from jellyfish contact. Moreover, she had extensive tentacle marks all over her legs (Thaikruea et al., 2012a). This incident prompted a more extensive response by the MOPH and marine biological team. However, one of the most often asked topics by local government officials and tour operators was whether or not venomous jellyfish constitute a significant concern in Thailand.

According to the box jellyfish survey, the information was collected by the marine and coastal resources department. Ten box jellyfish species were found in Thai water (the Andaman Sea and the Gulf of Thailand), including single-tentacle and multi-tentacles (Aungtonya and Chanachon, 2012; PMBC Database, 2020). Among these box jellyfish, the genus *Chironex* is infamous for its toxin-causing deadly instances worldwide. In Thailand, *C. indrasaksajiae* which has recently been

described as a new species of box jellyfish from the Gulf of Thailand is the most dangerous species (Figure 8b) (Sucharitakul et al., 2017). Another two unnamed species are *Chironex* sp.A found in the Andaman Sea (Figure 8a), and *Chironex* sp.C found in the western part of the Gulf of Thailand (Figure 8c).

Over the last fifteen years, there has been an increase in fatal and near-fatal box jellyfish envenomation cases in Thailand. Most of these cases were from medical records and patients from 1998 onwards. There were approximately 918 cases of envenomation which 8 case reports of death (Suntrarachun et al., 2001; Suriyan et al., 2019; Thaikruea and Siriarayapon, 2014, 2018; Thaikruea et al., 2012a; Thaikruea et al., 2012b). Six out of eight occurred on Pha-ngan and Samui islands, with the highest incidence of jellyfish-related deaths in Thailand (Thaikruea and Siriarayapon, 2016, 2018). According to the results of DNA analysis from tentacles and clinical features from the victims, 2 cases were confirmed to have been caused by *C. indrasaksajiae,* which was recently described as a new species of box jellyfish from the Gulf of Thailand (Sucharitakul et al., 2017).

Moreover, the usual envenomation cases occur each year, typically from August to November (Thaikruea and Siriarayapon, 2016). It correlated with the occurrence period of *C. indrasaksajiae* around this area, suggesting environmental conditions favor *C. indrasaksajiae*. Several mechanisms may be likely to contribute to more medusa abundance, such as more suitable environmental factors (Canepa et al., 2017), the effects of eutrophication (Ishii et al., 2008), overfishing (Lo et al., 2008), habitat modification for aquaculture and climate change (Dong et al., 2010). Another possibility is that it is a high tourist season on the islands. Logically, the more tourists there are on the islands, the more likely the jellyfish will come into contact. The full moon parties, which take place on Rin beach on Pha-ngan island every month on the night of the full moon, gather the largest crowds. Parties have increased in recent years, including black moon and half-moon parties. More importantly, the period that *C. indrasaksajiae* was found to be abundant was the Southwest Monsoon period, suggesting hazard management should readily cover this period. Since deaths related to *C. indrasaksajiae* envenomation have been reported in the Gulf of Thailand. However, the understanding of the specific toxicity and biology of this new species *C. indrasaksajiae* is awaiting the outcome of this study.

4. Box jellyfish venom

The complex mixture of bioactive compounds (venoms) that box jellyfish produced, was stored and delivered by cnidae. One form of cnidae, which is found in all cnidarians, is nematocyst (stinging cell) (Beckmann and Özbek, 2012a). The large portions of nematocyst tubules can penetrate the human dermis and inject the capsule's venom (Kitatani et al., 2015). Furthermore, when the nematocyst discharged (exverted or inside out), the venoms that have accumulated on the outside of the tubules are discharged as well (Rifkin and Endean, 1983). As a result, venom may be injected continually, rather than just when the tube is completely everted. Venom would be run off the tubules and passed through capillaries, adding to the quickness with which the envenomation occurs.

Cnidarian venoms have been studied extensively since the early twentieth century, and their toxicological variety has been demonstrated by various clinical observations and studies. The venoms of cnidarians are not well understood, however recently over 150 toxins have been found. They seem to be generally composed of a variety of protein enzymes (e.g. phospholipases A_2 and metalloproteases), pore-forming toxins, neurotoxins, and other non-protein bioactive compounds (e.g. serotonin, histamine, bunodisine, and caissarone) (Jouiaei, 2016).

Cubozoa includes various species of box jellyfish, which are generally classified into two distinct groups, that are harmful to humans. The morphological

differences between chirodropids and carybdeids indicate that the larger multi-tentacled chirodropids may be capable of injecting venom dosages far greater than those injected by the four-tentacled carybdeids. The venoms are stored in nematocysts and include a mixture of bioactive compounds. These compounds are either cytolytic, cytotoxic, inflammatory, or lethal. (Brinkman and Burnell, 2009). As of now, only a few individual venom proteins have been thoroughly investigated. However, increasing evidence suggests that cubozoan jellyfish produce at least one unique group of homologous bioactive proteins that are labile, basic, hemolytic, and similar in size (40–46 kDa) (Brinkman and Burnell, 2007; Nagai, 2003; Nagai, Takuwa, et al., 2000a; Nagai et al., 2002; Nagai, Takuwa, Nakao, Sakamoto, et al., 2000). Several *in vitro* and *in vivo* studies confirmed that these novel toxins are also potentially fatal. Moreover, they may produce cutaneous pain, inflammation, and necrosis in animals, which is comparable to the symptoms reported in envenomed humans (Auerbach et al., 2019b; Bailey et al., 2005; Bueno et al., 2021; Ramasamy et al., 2003; Ramasamy et al., 2004; S. Ramasamy et al., 2005a, 2005b; Winkel et al., 2005; Winter et al., 2007; Winter et al., 2008). Secondary structural studies and protein homology predictions indicate that the novel toxins may function as pore-forming toxins (Brinkman and Burnell, 2007; Parker and Feil, 2005). Despite the fact that pore-forming (cell-destroying) toxins are likely to present in all cnidarian venoms, they have been identified principally in the venoms of cubozoan. The biological activities of porins include hemolytic, myotoxic, cardiotoxic, and dermonecrotic effects (Jouiaei, 2016; Tibballs, 2018).

However, cubozoan venoms are typically similar in their biological activities, but the wide range and severity of the effects caused by different species suggest that their venoms differ in their protein composition, biological activity, and potency. This study reviewed the isolation of bioactive venom protein components, biological activity, biochemical characterization of cubozoan venoms, a particularly focusing on the genus *Chironex* which was responsible for the most deaths from jellyfish stings.

4.1 Isolation of jellyfish venom

Chironex venoms have historically been extracted from either entire tentacles or isolated nematocysts. These samples were extracted as either fresh, frozen, or lyophilized, with the latter (isolated nematocysts) being the most common method (Table 1) (e.g. Baxter et al., 1968; Bloom et al., 1998; Cantoni et al., 2020; Carrette and Seymour, 2004; Crone and Keen, 1969; Endean, 1987; Endean et al., 1969; Endean and Rifkin, 1983; T. E. B. Keen, 1971; Olson et al., 1984; Othman and Burnett, 1990; Wiltshire et al., 2000; Yanagihara and Shohet, 2012). Active venoms have been prepared and extracted using different techniques, including electrical discharge of nematocysts through human amnion (Crone and Keen, 1971), or mortar-and-pestle homogenization (Comis et al., 1989) and sonication of whole tentacles (Othman and Burnett, 1990). The use of entire tentacle extraction, on the other hand, has been questioned since jellyfish are never injected with tentacle tissue except for the components of the nematocysts.

In 1969, Endean *et al.* were the first researcher's group that achieved *Chironex* venom from isolated nematocysts by gently grinding thawed tentacles in a mortar and pestle to get crude nematocyst contents, then letting the mixture autolyze in sea water at 4 °C for 5 days to remove tentacle debris (Endean et al., 1969). Later, in 1998, Bloom *et al.* developed a subsequent modification of the venom preparation method in which whole tentacles were autolyzed in sea water at 4 °C for several days, followed by lyophilization of the isolated nematocyst precipitants. This method was an effective approach for preserving intact nematocysts containing bioactive components for more extended periods of time (Bloom et al., 1998), and after that, it has been routinely used by several jellyfish researcher groups (e.g. Bailey et al., 2005; Brinkman and Burnell, 2007; Carrette and Seymour, 2004; S. Ramasamy et al., 2005a). Afterwards, in 2012, Yanagihara and Shohet developed a new method of venom preparation from isolated nematocysts. The citrate solution, an acidic compound, was used to dislodge the nematocysts without breaking them. At 4 °C, this method can keep nematocysts intact for several years (Yanagihara and Shohet, 2012).

For extracting venom from the nematocysts, several protocols can be used. Venom can be obtained utilizing high pressure to force nematocyst disruption

(Yanagihara and Shohet, 2012), grinding with micrometer-size glass beads (Carrette and Seymour, 2004), or sonication of the nematocyst suspension in various buffers (Helmholz et al., 2007; Nagai, Takuwa, et al., 2000a; Reinicke et al., 2020; So et al., 2016). Afterwards, the sample is centrifuged to remove any remaining capsules, tubules, or tissue debris. Depending on the protocol, the venom sample contains varying amounts of proteins and peptides from nematocysts and varies in amounts of proteins and peptides from the tentacle debris. Accumulated research suggests that the most effective venom extraction method from nematocysts is using glass beads in homogenization (Frazao and Antunes, 2016).

[a] Sources of extracts include tentacle extract (T), milked venom (M) and nematocyst venom (N); subscripts L and M indicate lyophilized sources and venom isolated specifically from microbasic mastigophore nematocysts, respectively.

[b] Purification methods include size-exclusion (SE), cation-exchange (CEX), anion-exchange (AEX), and immunoaffinity (IA) chromatography; mAb indicates monoclonal antibodies; antibodies raised for IA and mAb studies are indicated in brackets; electrophoretic methods include native PAGE (NPAGE), PEG–capillary electrophoresis (PEG–CE) and SDS–capillary gel electrophoresis (SDS–CGE).

[c] The molecular mass of denatured proteins was determined by SDS-PAGE, unless SDS–CGE is specified; major proteins are shown in bold.

[d] Biological activities: lethal (L), cardiotoxic (C), hemolytic (H), dermonecrotic (D), pore-forming in lipid membranes (Pþ), musculotoxic (M), induction of immunological response (IR) and hepatotoxic.

4.2 Bioactivity of the genus *Chironex* venom

Following five decades of research, the genus *Chironex* (especially *C. fleckeri*) has become the most extensively studied cubozoan jellyfish. Early studies on whole tentacle and nematocyst extracts have reported several biological activities associated with *C. fleckeri* venom proteins, including cardiotoxic, hemolytic, dermonecrotic, neurotoxic and immunological effects (Baxter et al., 1968; Bueno et al., 2021; Crone, 1976; Crone and Keen, 1969; Endean et al., 1969; Endean et al., 1993; Shirley E. Freeman, 1974; Shirley E Freeman and Turner, 1969; Horiike et al., 2015; Piontek et al., 2020)

4.2.1 How box jellyfish venom kills, stopping the heart in a short time in five minutes : the cardiovascular effects and hemolytic toxic effects

The difficulty of investigating the lethality of *Chironex* venom was differences in the source of jellyfish venom and the units of reported lethal dose that depend on each research group. However, extensive experiments of envenomed on different animals, which include fish, prawns, crayfish and mice, rats, rabbits, guinea pigs, sheep, rabbits, and monkeys revealed that venom caused the heart to fail to relax progressively and it became paralyzed in systole (Brinkman and Burnell, 2009; Endean et al., 1969). Currently, there appear to have two scientific hypotheses of lethal effect that support the idea of how box jellyfish venom kills and stops the heart within minutes: the cardiovascular effects and the hemolytic effects.

Firstly, the cardiovascular effects that the venom acts directly on the heart make the vasoconstrictor effects on other parts of your body less effective. Moreover, Ramasamy et al. in 2004, indicated that acute cardiovascular effects from *Chironex* venom are more likely to cause rapid death than respiratory arrest (Ramasamy et al., 2004). Despite many decades of investigation, the mechanism behind the fatal impact of *Chironex* venom has remained unknown. The prevailing hypothesis was that the culprits are ion channel blockers, molecules that interfere with the flow of ions into and out of cells. As a result, nerve and muscle cells cannot work properly, including those that control the heart pumping due to these

blockages. Early studies suggested that venom-induced calcium ion (Ca^{2+}) transport across muscle fibre membranes plays an important role in muscle contracture and paralysis (Joseph W Burnett and Calton, 1983; Endean, 1987; Endean and Henderson, 1969). The study by Mustafa and colleagues found that the toxin increases sodium influx into the cells and subsequently increases calcium via the sodium/calcium ion exchange mechanism resulting in calcium overload. This may induce arrhythmias and lead to sudden death (Mustafa et al., 1995; Vassalle and Lin, 2004). Afterwards, Cheng claimed that the toxin might comprise fibrinolysins, phospholipases, proteases, hyaluronidases, collagenases, kinins, vasoactive amines (such as histamine), and catecholamines. The toxin acts directly on the myocardial, neurologic and hepatic tissue, disrupting cell membranes and releasing inflammatory mediators. However, this assumption is not supported by research or pathophysiological explanations (Learmont, 2006). Moreover, Bailey et al. (2005) suggested that the rapid influx of Ca^{2+} into cardiac cells could be attributed to the indiscriminate entry of ions via large pores in the cell membrane formed after exposure to *Chironex* venom rather than via Ca^{2+} channels. Another study about a direct action of venom on cardiac and vascular muscle was observed by Hughes et al. (2012). They treated cardiac and vascular tissues of rats with unpurified extracts from nematocysts. It caused atrial standstill and negative inotropy that were unaffected by propranolol, atropine, or CGRP8-37. In addition, it caused contraction of small mesenteric arteries that was unaffected prazosin, bosentan, or tetrodotoxin. Therefore, the investigators concluded that the venom had no effect on autonomic nerves, postsynaptic α1or β1-adrenoreceptors, muscarinic, endothelin, or CGRP receptors. However, the venoms may involve direct effects on cardiac and vascular muscle. More recently, Pereira and Seymour (2013) showed in vitro that *C. fleckeri* venom, in contrast to *Carukia barnesi* venom, is highly toxic to human cardiac and skeletal muscle cells. All these studies suggest that severe hypotension caused by the venom is due to direct cardiotoxicity, which overwhelms any peripheral vasoconstrictor effect.

Secondly, the hemolytic toxic effects of pore-forming protein on red blood cells or porin could be considered a candidate for the fatalities. According to Yanagihara's theory, the venom of box jellyfish contains proteins that break down red blood cells and allow potassium to be released. The release of K+

causes a disruption in the electrical rhythms that keep the heart pumping, which ultimately results in the heart suspending its contractions. Not only ion channel blockers in venom, but also many “porins”: proteins that puncture cells, allowing their contents to leak out (figure 9). In 2012, Yanagihara and a colleague reported that venom of *Chironex fleckeri*, rapidly punctures red blood cells, causing them to leak a huge amount of potassium ions. A high level of potassium in the blood, or hyperkalemia, causes cardiac arrest, and when the mice was injected with high doses of venom, their hearts quickly stopped. The same happened when the mice was injected only the porins from the venom. This study also agreed with Yanagihara's theory that suspected porins might be the lethal components by causing the destruction of red blood cells.

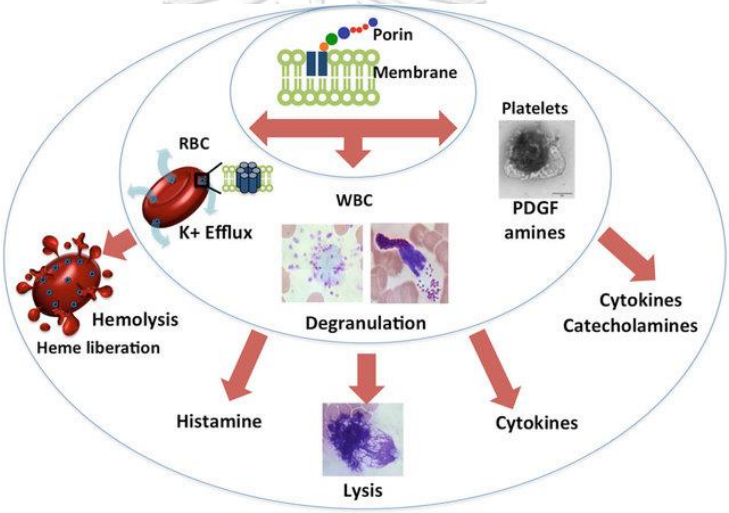

Figure 9 Schematic of the hypothesis of venom-porin initiated mechanism of potassium, catecholamine and cytokine release. Cubozoan venom porin injected into the blood stream inserts and self assembles to form pores on target cell plasma membranes causing target cell effects. Source : Yanagihara, Wilcox, Smith, et al. (2016)

4.2.1.1 Pore-forming protein toxin (PFTs)

Chironex venom contains potent pore-forming toxins (PFTs), also known as porin, cytolysin or hemolysin. Early studies of box jellyfish venom suggested that hemolysins have not been considered to be lethal (Bailey et al., 2005). However, it has been discovered that a catastrophic hyperkalemic state precedes clinically measurable hemolysis and that this is caused explicitly by the cubozoan venom PETs (Yanagihara and Shohet, 2012). These toxins appear to function simply by forming pores in cell membranes, disrupting the permeability barrier and leading eventually to cell death.

Generally, there are three major steps in the generation of pores by PFTs, summarized in figure 10 (Anderluh and Lakey, 2008; Parker and Feil, 2005). The organisms synthesize PFTs as soluble units (mostly monomers, dimers or oligomers). Second, upon soluble binding units to lipid membranes, they form oligomers at the surface of the membrane (self-assembly). In most cases, these membrane-bound complexes form an ordered complex called a pre-pore, which is not yet functional. Finally, these membrane-bound complexes undergo conformational changes, and become inserted into the lipid membrane bilayer, forming a functional pore. The binding to lipid membranes sometimes depends on the presence of specific receptors, such as lipids (sphingomyelin, cholesterol, etc.), glycolipids, or glycoproteins (Podobnik and Anderluh, 2017).

PFTs can be classified into two families, depending on secondary structure as the α-helical or β-barrel structural features of their transmembrane channel (as described by Gouaux, 1997). The α-PFTs are predicted to form pores using helices. These toxins tend to be highly α-helical, with the larger toxins having pore-forming domains consisting of a three-layer structure of up to ten α-helices sandwiching a hydrophobic helical hairpin in the middle of the structure. This hairpin is thought to drive the initial steps of the insertion process. Second group, the β-PFTs are named because of their structural characteristics composed mostly of β-barrel domains. These toxins tend to be rich in β-sheet (Parker and Feil, 2005).

Full amino acid sequence analysis and molecular modelling, show that the porin has structural motifs familiar with self-assembling bacterial porins, such as anthrolysin O and streptolysin O (Bernheimer et al., 1979). Afterwards, Chung et al. (2001) reported on the first hemolytic porin from *Alatina* sp. (previously reported as *Carybdea alata*). Since then, all cubozoan venom has been found to have close homologous proteins. In *C. fleckeri* venom, there are two different isoforms of this porin (MW 43 and 45 kDa) (Brinkman and Burnell, 2009; Nagai, Takuwa, Nakao, Sakamoto, et al., 2000; Yanagihara, Kuroiwa, Oliver, Chung, et al., 2002). Moreover, secondary structure analysis and remote protein homology predictions suggest that the family of box jellyfish toxins (CfTXs, CqTX, CrTX and CaTX) may act as α-PFTs, with three-domain Cry-like toxins. These domains were estimated to play an essential role in membrane penetration and pore-forming after binding to the specific receptors (Brinkman and Burnell, 2009; Podobnik and Anderluh, 2017). Thus, the fact that porins are conserved across all cnidarian species supports the concept that these proteins are key venom components and play an important role in the clinical symptoms of cubozoan stings (Yanagihara, Wilcox, Smith, et al., 2016).

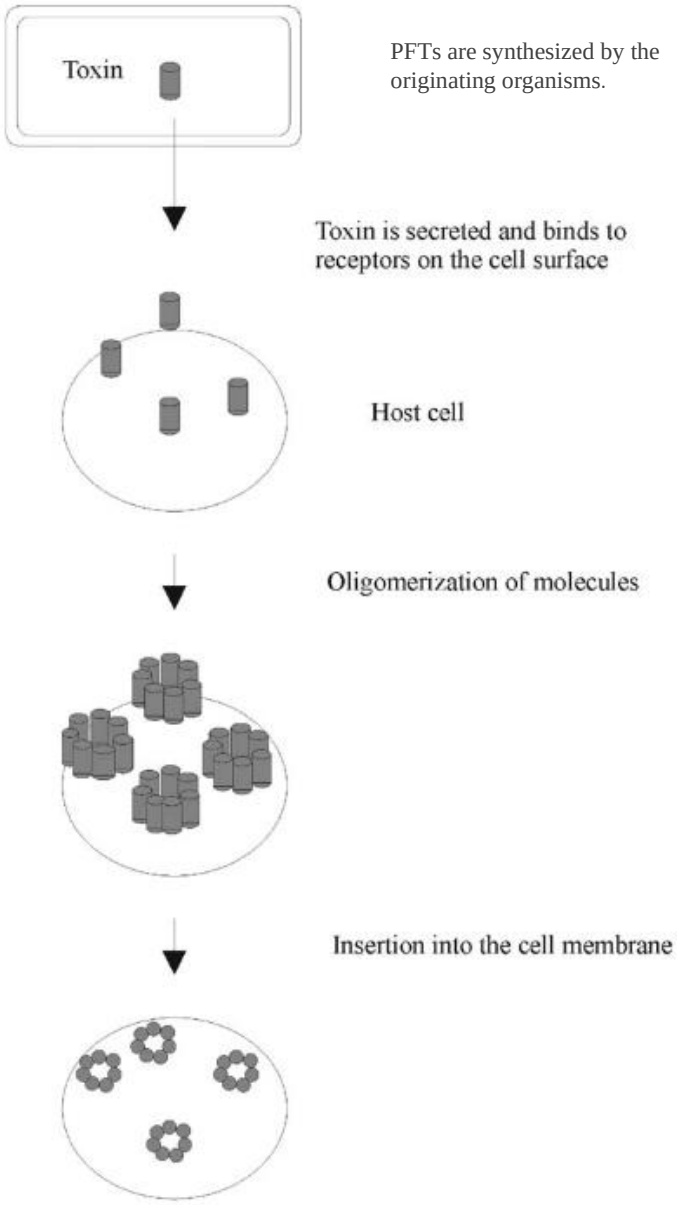

Figure 10 The 3 major steps involved in membrane pore formation generated by PFTs. Source : Parker and Feil (2005)

4.2.2 Severe pain and dermatotoxic effects

The studies by Shirley E Freeman and Turner (1969) and T. E. B. Keen (1971) showed that a dermal necrosis factor isolated from the venom caused rapid skin death in experimental animals. This symptom was similar to that seen in human skin too. For human dermal necrosis, the lesions appear to whip-like with a purple to brown color; the wounds are associated with erythema, oedema, and vesicle formation and may progress to full-thickness necrosis within the first two weeks after stinging. Long-term complications may include keloids, granulomas, hyperpigmentation, fat atrophy, and muscle contractures (Figure 11) (Thaikruea and Siriarayapon, 2015a).

Figure 11 Wound characteristics; (A) on the sixth day, (B) on the fifth day with small blisters developed, (C) on the 14th day with turned wound to crusts with moderate to severe itching, and (D) on the 61st day, dark brown tentacle arks remained on patient's knee with smooth skin. Source : Thaikruea and Siriarayapon (2015a)

Several researchers have attempted to elucidate the mechanism underlying the severe pain and inflammation caused by *C. fleckeri* venom. Inflammatory pain is mediated by several chemical components, which act on pain receptors (nociceptors) directly or indirectly via complex signaling pathways (figure 12)(Baxter et al., 1968; Brinkman, 2008; Shirley E Freeman and Turner, 1969; T. Keen and Crone, 1969). In a recent study involving *Chironex* tentacle extracts, the burning sensation associated with cnidarian envenomation was linked to the activation of transient receptor potential vanilloid-I (TRPV1) channels in nociceptive neurons (Cuypers et al., 2006). Moreover, CfTX-1 and -2 proteins isolated from *C. fleckeri* venom, are thought to be responsible for skin inflammation and necrosis (Auerbach et al., 2019a).

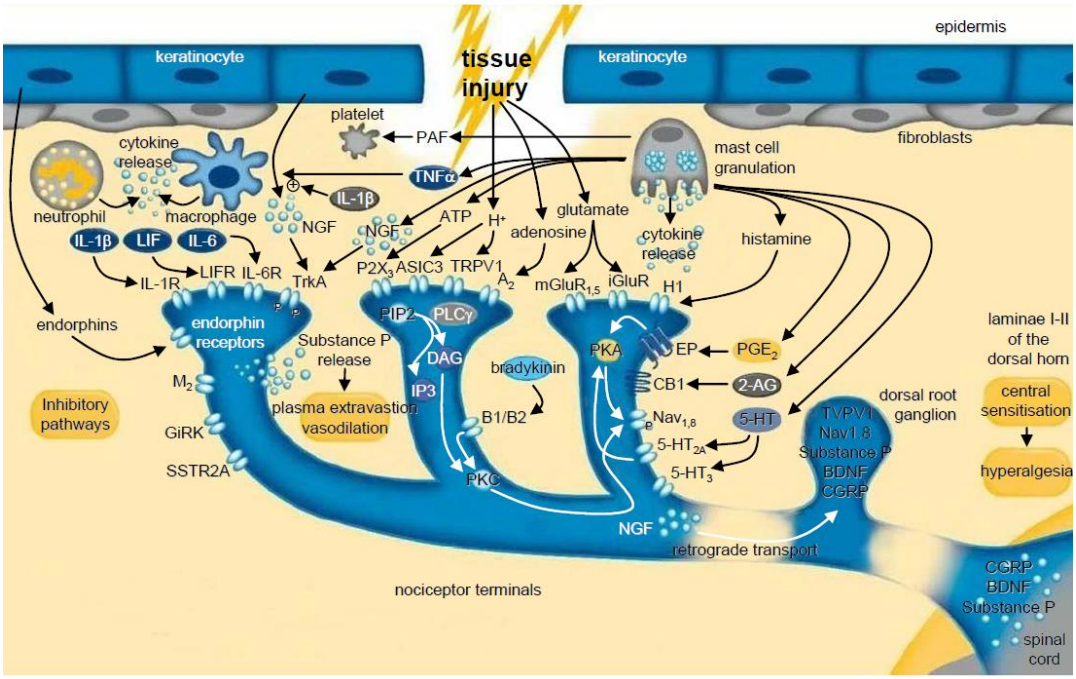

Figure 12 Mediators and signaling pathways involved in inflammation and pain. Source : Brinkman (2008)

4.2.3 Neurotoxic effects

Endean et al. (1993) isolated a neurotoxin (T4; 150 kDa) that blocked conduction in the isolated sciatic nerve of the toad and produced a progressive reduction in the response of the rat diaphragm to phrenic nerve stimulation. In 2003, Ramasamy and colleagues also investigated the neurotoxicity of the *C. fleckeri* venom on the chick biventer cervicis nerve muscle. Venom (50 mg/ml) significantly inhibited indirect and direct twitches of the biventer nerve muscle. However, the isolated neurotoxic proteins of this study may be assumed to be different toxins producing the neurotoxic effects observed in the study of Endean. They suggested that the differences were because of venom concentration differences or inactivation during the venom extraction process (Ramasamy et al., 2003).

4.2.4 Immunological effects

Immunological issues of *C. fleckeri* envenomation and other jellyfish envenomation have not been given much attention. With so many foreign proteins and bioactive components being deposited into the human dermis and blood during envenomation, it's no surprise that immune reactions are common (Tibballs, 2018). According to O'Reilly et al. (2001) study, of 19 patients of *C. fleckeri* envenomation, 11 patients (58 %) had delayed hypersensitivity responses that healed either spontaneously or with an oral antihistamine and a topical corticosteroid.

Dermatitis caused by jellyfish stings can be characterized as 3 types of immune reaction, i.e., immediate allergic, late-phase reaction and relapsing allergic response, which correspond to clinical reactions (Asztalos et al., 2014). According to Horiike et al. (2015) study, the isolated CqTX-As (45 kDa) from *Chironex yamaguchii* venom were use as allergens for the prick test. Only an immediate allergic response, such as itching and erythema, was detected in the test. Moreover, they detected the IgG-binding acidic glycoprotein (of 30 and 66 kDa) in the nematocyst capsule wall and spine, and also identified CqTX-A protein the nematocyst. They found that this protein, the major toxic protein, is also a heat-stable

IgE-binding allergen. The detection of these proteins might explain why some people have both immediate allergy-toxic and persistent allergic reactions.

5. Clinical effects of *Chironex* envenomation

5.1 Symptoms

Extreme pain, impaired consciousness, dyspnoea (breathing difficulty), cardiac dysfunction, pulmonary oedema, shock, hypertension and hypotension, rapid acute cutaneous inflammation (dermonecrosis), and permanent scarring are some of the clinical symptoms of *Chironex* envenoming. Respiratory and cardiac failure may occur within a few minutes in the most severe cases (Beadnell et al., 1992; Brinkman and Burnell, 2009; Lumley et al., 1988; Williamson et al., 1984a).

Millions of cnidae are discharged into the skin when a Chironex tentacle touches a victim's skin. The tubules of the discharged nematocysts penetrate the epidermis and into the underlying vascular and nerve-rich dermis, delivering venom into the surrounding tissue (Figure 13) (Yanagihara, Wilcox, Smith, et al., 2016). Lymphatic and capillary vessels easily absorb venom, although the absorption rate depends on the venom dosage and peripheral circulation, which is regulated mainly by the muscular activity of surrounding tissues (Brinkman, 2008; Joseph W. Burnett, 1991; Fenner, 1991; Williamson et al., 1996). Envenomation is especially dangerous for children because of their greater surface area to mass ratio and absence of body hair, which causes the tentacles to contact into direct touch with their skin (Fenner and Harrison, 2000). Moreover, many factors affect the pathophysiology of a jellyfish sting. These depend on the number and type of nematocysts, the wound site, the skin thickness, the patient's health, and the condition of envenomated tissue (Yanagihara, Wilcox, Smith, et al., 2016).

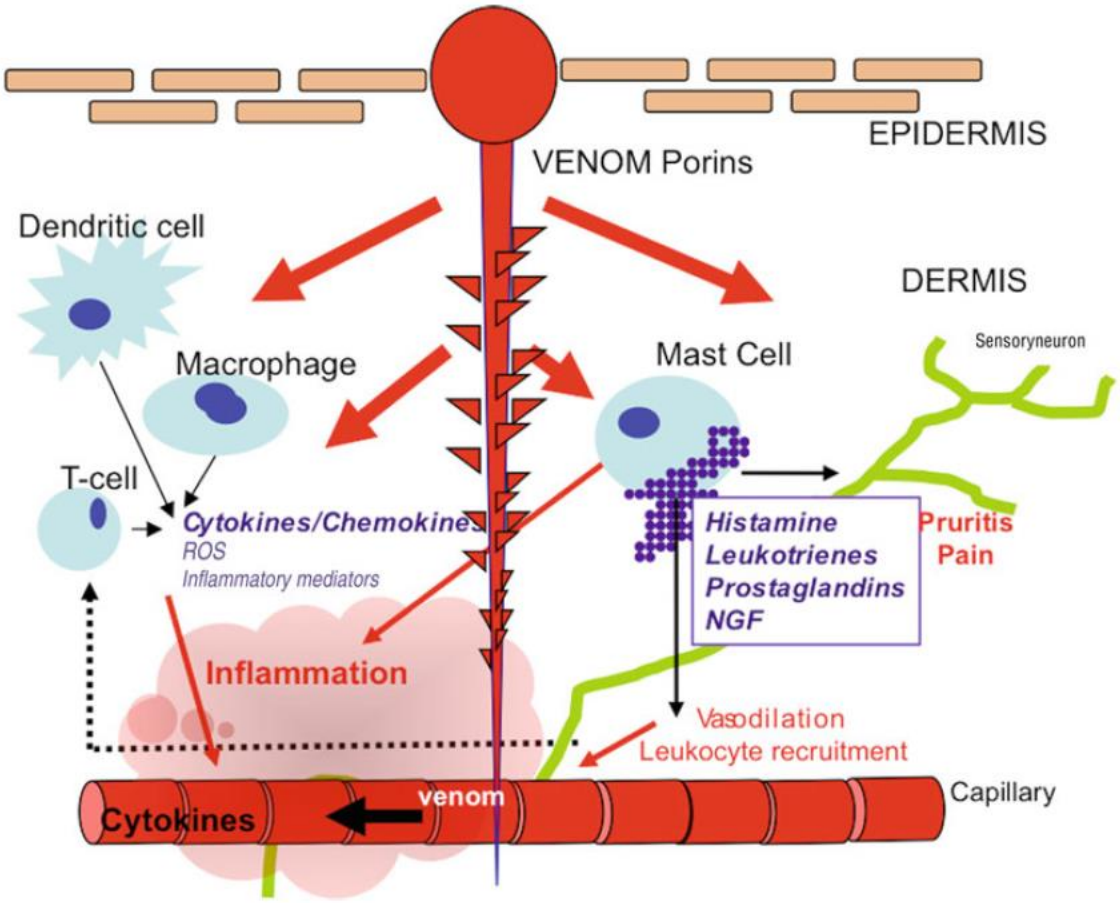

Figure 13 Illustration of discharged eurytele nematocyst structures. Source : Yanagihara (2016)

Porin-based puncture of erythrocytes causes a rapid and potentially lethal due to leakage of potassium ions from red blood cells into the plasma before the pore on erythrocyte expansion is enough to enable the release of the big tetrameric haemoglobin molecule. Moreover, when porins are exposed to the system, the platelets may be ruptured and the resulting foam cells can develop, causing an explosion of histamine, inflammatory cytokines, and other chemokines to life-threatening levels (Yanagihara, Wilcox, Smith, et al., 2016).

At the envenomation site, severe pain, oedema, and linear wheals with white ischaemic centers surrounding vivid erythematous flares have occurred (Joseph W. Burnett, 1991). These symptoms can last for days or even weeks. As a result of this, Yanagihara, Wilcox, Smith, et al. (2016) suspect that leakage of white blood cells and platelets that are the source of catecholamines, biogenic amines, and

cytokinesis caused these symptoms of envenomation. More than 300 different chemicals are stored in platelets and their granules, which are released uncontrolled when porin is operated (Ren et al., 2008; Whiteheart, 2011). This group of compounds includes small biogenic amines (like histamine and serotonin) and cytokines (like platelet-derived growth factor (PDGF), tumor necrosis factor-alpha (TNF-), interleukin-7 (IL-7), and endothelial growth factor (EGF), as well as small peptides (like dopamine and serotonin) (EGF). In addition, white blood cells have a lot of inflammatory cytokines and other biogenic amines that can be released when porins start breaking down (Yanagihara, Wilcox, Smith, et al., 2016). Similar to the study of Williamson et al. (1984b), they suggested that the acute inflammatory response evoked by *C. fleckeri* venom may be caused by the release of compounds such as histamine, serotonin, bradykinin, and perhaps prostaglandins. As a result of these findings, it seems that porin is both the fastest-acting fraction and sufficiently deadly to be the most significant venom component in terms of clinical symptoms, and thus porin blockage should be a primary aim for treatment.

5.2 Treatments

5.2.1 First aid with vinegar

Contacting jellyfish tentacles with human skin causes thousands of nematocyst tubules to be injected into the epidermis and dermis, causing both local and systemic injury (Tibballs et al., 2011). The goals of first aid are to reduce the amount of venom released from the nematocysts that have not been discharged and to relieve pain. Avoid rubbing the wound, and immediately rinse the stinging area with vinegar for at least 30 seconds to deactivate any remaining undischarged nematocysts. Freshwater should not be applied since it prompts the nematocysts to discharge. Seawater should be utilised if vinegar is unavailable (Lakkis et al., 2015; Premmaneesakul and Sithisarankul, 2019). According to the protocol of expert opinions on jellyfish envenomation especially box jellyfish envenomation, after vinegar pouring jellyfish tentacles often detach on their own. If

the skin remains adhered, it should be pulled off with forceps, but only after the vinegar has been applied (Thaikruea et al., 2020).

5.2.2 Antivenom

The only jellyfish antivenom manufactured worldwide is *Chironex fleckeri* antivenom, which has been used since 1970 (Tibballs, 2018; Winkel et al., 2003). In severe cases of *C. fleckeri* envenomation, administering the commercially available CSL box jellyfish antivenom is recommended (Tibballs, 2006a). CSL box jellyfish antivenom prepared from the sera of sheep that have been hyperimmunized with *C. fleckeri* milked venom (Barnes, 1967). It significantly reduces the acute inflammatory response of the skin at the site of envenomation; however, it is not known whether its effect lessens long-term scarring (Williamson et al., 1984b). Each ampoule of antivenom contains sufficient activity to neutralize 20,000 intravenous LD_{50} mouse doses. The recommended dose is three or more ampoules on theoretical and experiential grounds for resuscitation, analgesia, and skin-sparing cosmetic effects (Sutherland, 1992). However, the use of antivenom has minor side effects, including cutaneous rashes. Therefore, administration of the antivenom is indicated only in significant envenomations, such as those associated with cardiorespiratory instability or severe pain, and its use is restricted to trained personnel (Bailey et al., 2003). Afterwards, co-administration of CSL box jellyfish antivenom with verapamil (calcium channel blockade) and magnesium sulphate ($MgSO_4$), was a more effective therapy in countering the actions of venom (Ramasamy et al., 2004). However, there is no clearly effective specific therapy available. The current antivenom is used without clinical validation and has been linked to negative outcomes of envenomations. Moreover, clinical evidence for using *C. fleckeri* antivenom in other species is limited, and it is not available in Thailand (Premmaneesakul and Sithisarankul, 2019; Suntrarachun et al., 2001).

5.2.3 Zinc and copper gluconate

Pore-forming toxins (PFTs), or porins, are the most rapidly acting and lethal components. This protein is the most significant venom component in terms of clinical symptoms. Thus, effective therapeutics for cnidarian envenomation will target the blockade molecules of these pore-forming toxins (PFTs), as well as other membrane perturbance (MPs) (Yanagihara, Wilcox, Smith, et al., 2016). Porin insertion affects the permeability barrier of the cell membrane, allowing monovalent ions to flow. In particular, the efflux of K^+, the influx of Na^+, the influx of Ca^{2+}, and the efflux of CI^- all result in depolarization of the cells due to the rapid equilibration of the internal and external ionic solutions. With enough size and duration of open time, bigger molecules such as intermediates in metabolism (e.g., nucleotides and sugar phosphates) would be allowed to flow out of the pores and cause cell death, also known as pyroptosis, which is represented as a loss of cellular function. Consequently, large proteins such as haemoglobin and lysosomal enzymes leak from red blood cells (RBC), resulting in hemolysis and tissue necrosis (Bashford et al., 1985).

Pore-forming toxins are classified into broad classes based on their secondary structure, with some requiring Ca^{2+} for self-assembly polymerization to form functional transmembrane pores. Because of this, some divalent cations, including Zn^{2+}, Cu^{2+}, and Mg^{2+}, may be able to competitively bind to calcium-binding sites and lead to inhibiting calcium-dependent porin proteins from self-assembling into polymeric pores. In addition, zinc has been reported to have membrane-protective functions in the presence of membrane-disrupting molecules and toxins (MPs) (Yanagihara, 2013).

According to Yanagihara (2019), copper gluconate alone is significantly more effective at reducing venom-induced cell hemolysis than zinc gluconate alone or combined with copper gluconate. In the study, human RBCs were incubated with 5 units/mL/% RBC *Alatina alata* venom, zinc gluconate, and copper gluconate at increasing doses for 1 hour at 37 °C. Per cent hemolysis was determined by OD_{405}. As a result, it was determined that copper gluconate is active at approximately 30 µM or greater for box jellyfish venom hemolysis inhibition,

whereas zinc gluconate is active at approximately 300 μM or greater. Copper gluconate is approximately ten times more potent than zinc gluconate alone in inhibiting box jellyfish venom. Herein, copper gluconate was used to investigate hemolysis inhibition of the *C. indrasaksajiae* venom.

5.2.4 Hot water immersion

Immersion in hot water (45 °C) is a well-established and widely recommended treatment for marine envenomations, including severe pain from echinoderm and venomous fish stings (Buckley and Isbister, 2012; Ongkili and Cheah, 2013). Immersing the sting location with hot water is considered to deactivate key components of marine venoms, although the exact mechanism of action remains unclear. Other researchers suggested that the temperatures required for such inactivation are significantly higher (60 °C), and that the pain relief experienced during hot-water immersion is the result of physiological responses to the heat application rather than a chemical event (such as increased subcutaneous blood flow) (Wilcox and Yanagihara, 2016). The widespread hypothesis is that the temperatures were used to inactivate venom components. Several in vitro and in vivo investigations indicate that cnidarian venoms from all classes within the phylum are heat-labile (Table 2). Another possibility is that hot-water immersion has a direct potential therapeutic impact on pain receptors, decreasing perceived pain (Muirhead, 2002). Herein, temperatures were utilized in this study to determine the inactivation of *C. indrasaksajiae* venom components.

Table 2 Published evidence of heat inactivation of cnidarian venoms or venom components at temperatures (Adapted from Wilcox and Yanagihara, 2016)

Study	Species	Methods	Results
Baxter & Marr (1969)	*Chironex fleckeri* (Cubozoa)	Venom heated to 30, 40, 50, 60, or 70 °C for 10 min Rapid exposure: venom brought "quickly" to 44, 47, 50, 53, 56, or 59 °C and immediately chilled	10 min exposure: activity lost between 40 and 50 °C Rapid exposure: activity lost at >53 °C
Endean & Henderson (1969)	*Chironex fleckeri* (Cubozoa)	Venom incubated at 37, 42 or 45 °C for 5, 10, 15 or 20 min	Activity lost between 40–42 °C Barnacle muscle contraction (all activity lost if heated at 42 °C for 5 min, but activity remained after heating at 40 °C for 20 min)
Chung et al. (2001)	*Alatina alata* (formerly *Carybdea alata*; Cubozoa)	Venom serially diluted and maintained at 4, 25, 37, 45, 60 or 100 °C for 30 min	Venom potency decreased when exposed to temperatures above 25 °C; activity was "sharply reduced" at 45 °C, and abolished entirely at 100 °C
Monastyrnaya et al. (2002)	*Radianthus macrodactylus* (Anthozoa)	Isolated cytolysins heated briefly to 35, 45, 60, and 80 °C	Activity decreased linearly with increasing temperature; at 35, 45, 60, and 80 °C caused the loss of 6, 18, 95, and 100% of their initial hemolytic activity.
Carette et al. (2002)	*Chironex fleckeri* (Cubozoa)	Venom incubated at 4, 21.5, 33, 39, 43, 48, 53, or 58 °C for 2, 5, or 20 min	Activity decreased overall with increased temperature and duration of exposure. All activity lost at 20 min of 43 °C or 5 min of 50 °C
Koyama et al. (2003)	*Chiropsalmus quadrigatus* (Cubozoa)	Venom heated to 40 °C for 10 min	Significant attenuation of activity
Marino et al. (2004)	*Aiptasia mutabilis* (Anthozoa)	Venom incubated at 4 °C, 20 °C, 40 °C and 60 °C for 5, 30 or 60 min	All activity lost at 60 °C; activity reduced in a time- and dose-dependent manner at lower temperatures
Noguchi et al. (2005)	*Chiropsalmus quadrigatus* (Cubozoa)	Venom heated to 50 °C for 10 min	All activity lost
Kang et al. (2009)	*Nemopilema nomurai* (Scyphozoa)	A: venom incubated at 4, 20, 40, 60 and 80 °C for 60 min B: venom incubated at 40 °C for 0, 10, 30, 120 or 360 min	A: all activity lost at temperatures > 60 °C, attenuation of activity in 40 °C incubated venom B: activity reduced in a time- and dose-dependent manner
Feng et al. (2010)	*Cyanea nozakii* (Scyphozoa)	Venom incubated at 35, 50, 65 and 80 °C for 20 or 40 min	All activity lost at temperatures > 65 °C; activity reduced in time- and dose-dependent manner
Cuiping et al. (2011)	*Cyanea nozakii* (Scyphozoa)	Venom incubated at 20, 40, 60, and 80 °C for 10, 30, or 50 min	Nearly all activity lost at 60 °C for even 10 min; activity lost with increased temperature and incubation time
Pereira & Seymour (2013)	*Chironex fleckeri* (Cubozoa)	Venom incubated at 24, 37, 44, 46, 48, 50, 60, or 100 °C for 20 min	All activity lost at 44 °C for cardiomyocytes and at 48 °C for skeletal myocytes (80% survival at 44 °C)
Li et al. (2013)	*Stomolophus meleagris* (Schyphozoa)	Isolated venom toxin (SmTX) incubated at 4, 15, 25, 37, 45 and 60 °C for 30 min	Activity decreased with temperature above 37 °C
García-Arredondo et al. (2014)	*Millepora complanata* (Hydrozoa)	Venom incubated at 4, 25, 37, 45, 60 and 100 °C for 30 min	Activity decreased at temperatures ě 45 °C in a dose-dependent manner
Hernández-Matehuala (2015)	*Millepora alcicornis* (Hydrozoa)	Venom incubated at various temperatures between 0 and 100 °C for 60 min	Activity sharply decreased when incubated abouve 40 °C, with >50%

CHAPTER III

Cnidae characterization and optimization of venom extracted from Thai multi-tentacle box jellyfish (*Chironex indrasaksajiae*) by bead homogenization

1. Introduction

Box jellyfish envenomation is becoming an important public health concern in Thailand due to many fatal and severe cases caused by these creatures. *Chironex indrasaksajiae* and *Chiropsoides buitendijki* are multi-tentacle box jellyfish in Thai waters (PMBC Database, 2020). According to the fatal cases, *Chironex indrasaksajiae* is considered as the most venomous box jellyfish in Thai waters that caused death 7 out of 8 cases with dying 2-5 minutes after being stung (Fenner et al., 2010; Sonthichai et al., 2016; Thaikruea and Siriarayapon, 2016; Thaikruea et al., 2012a; Thaikruea et al., 2012b). According to the box jellyfish survey, *Chiropsoides buitendijki* is the most abundant species of box jellyfish in Thai water and can be found 100-200 individuals per net per hour in the blooming season of jellyfish (Yongstar, 2017). There are no reports of fatal cases from *C. buitendijki* in Thai waters. Although *Chiropsoides* envenomation is rare to be as severe as *Chironex*, it can cause severe pain, redness, and swelling in the stinging area of the skin (Thaikruea and Siriarayapon, 2018).

Box jellyfish belong to class Cubozoa, phylum Cnidaria which their cube-shaped medusae can distinguish. Their defining feature of this phylum is a stinging organelle called “cnidae” which are specialized membrane-enclosed cellular organelles or secretions of the Golgi apparatus capable of explosive discharge on the activation of cnidocytes (Beckmann and Özbek, 2012b; Fautin, 2009; Özbek, 2011). Cnidae have been distinguished into three broad types: penetrant nematocysts, the volvent spirocyst (Mariscal, McLean, et al., 1977) and the glutinant ptychocyst (Mariscal, Conklin, et al., 1977). In cubozoa, nematocysts are the only type of cnidae that comprise the cnidome and three main categories of nematocyst are commonly found: mastigophore, euryteles and isorhizas (Gershwin, 2006; Jouiaei, 2016; Östman, 2000). The study of cnidome, and also information upon morphology of cnidae, are now regarded as an important part of jellyfish species identification

(Acuna et al., 2003; Conklin et al., 1977; Östman, 1982; Ryland et al., 2004). Moreover, each type of nematocysts has been described based on the structure of each type (Rifkin and Endean, 1983). Consequently, the toxin should differ amongst nematocyst types (Carrette et al., 2002). Subsequently, the variation in nematocysts ratio could reveal the level venom variation of each species (Killi et al., 2020). This is the first time that the cnidomes of *C. indrasaksajiae* and *C. buitendijki* have been found.

Moreover, box jellyfish venom has attracted researchers because of its toxic properties that cause death within minutes. The biologically active components in the venom of these Thai multi-tentacle box jellyfish have not been isolated, and the mechanism of their toxicity has not been studied yet. The crucial and primary step of venomics is to optimize the conditions and methods of venom extraction for maximum recovery of venom. For decades, acquiring pure box jellyfish venom stored in millions of cnidae has been a major challenge for researchers. Due to the difficulty of obtaining high quantities of venom from these organelles, various novel venom extraction techniques have been developed. Initial venom extraction experiments, for example, focused on natural nematocyst discharge, which required an electrical simulation to rupture the cnidae membrane of the fresh tentacles placed over a human amniotic membrane (Barnes, 1967). The possibility of sample contamination from the amniotic membrane led to efforts to improve mechanical disruption techniques. After that, mortar and pestle grinding in ice and filtered seawater (Endean et al., 1969; Endean and Rifkin, 1983; Endean et al., 1991) were used to extract the venom. Tentacle homogenization followed by low-temperature centrifugation was also used to extract the venom. Sonication with high sound frequencies to rupture nematocysts was also used (Bloom et al., 1998; Mustafa et al., 1995). Poor volume recovery and low yields of venom proteins were problems with these procedures, and venom extracts mixed with extraneous proteins from tentacle rather than pure cnidae content (Cantoni et al., 2020). In 2004, Carrette and Seymour presented a protocol for an extraction procedure that was both quick and repeatable, resolving issues that had arisen in the past. With glass beads and a bead beater, freshly isolated nematocysts (Bloom et al., 1998) were manually burst in MilliQ water at 4°C to avoid heat built-up. By using centrifugation, the venom was isolated from the cnidae structural

components and the tentacle debris. This approach has been applied in numerous box jellyfish venom research due to the rapid and repeatability of the procedure (Carrette and Seymour, 2004). In 2012, Yanagihara and Shohet developed methods of venom preparation and extraction to recover venom yields with high specific activity (Yanagihara and Shohet, 2012). With the use of trisodium citrate to cytolyze the tentacles that were freshly excised from the beachside. This technique gets maximizes recovery of intact cnidae from tentacles (>90% of all cnidae) compared to the venom preparation method of Bloom et al. (1998).

Further research is required to understand the mechanisms of venom activity and the appropriate treatments for envenomation. The isolation of bioactive jellyfish venom is required as one of the initial steps in this procedure. Thus, this chapter aimed to optimize the venom extraction protocol from the cnidae isolated from the whole tentacle to acquire the highest protein yield to be researched further for the effects of these box jellyfish according to Yanagihara and Shohet (2012) procedure of venom preparation and Carrette and Seymour (2004) for venom extraction method by using bead homogenization.

2. Materials and methods

2.1 Jellyfish collection

The animal collection was done according to the approved protocol by the Mahidol University-Institute Animal Care and Use Committee and the Mahidol University Biosafety Committee (see appendix Biohazard Control Plan). The matured specimen of *C. indrasaksajiae* was captured near the coastal zone at Chaloklum Bay in Koh Pha-Ngan (Suratthani, the Gulf of Thailand) in August 2019 (Figure 14) that is the seasonal of jellyfish occurring in this area (see appendix Figure A5). The green spotlight was used to look at them at night and picked the jellyfish up by using a fishing net that had a plastic bag inside to prevent the attachment of the tentacles to the net. (Figure 15B)

During the survey and collection of box jellyfish samples at Libong Island and Sikao Bay in September 2020 (Trang, the Andaman Sea, Thailand) (Figure

14), *C. buitendijki* was found that is also the seasonal of jellyfish occurring in this area (see appendix Figure A6). This is considered a good opportunity to represent the less venomous multi-tentacle box jellyfish compared to the deadly venomous ones (*C. indrasaksajiae*). A total of 102 *C. buitendijki* samples were collected by using the shrimp trammel net on transects along with the water current for 1 hour (Figure 15A). The net was 140 meters long and 1.4 meters wide. The trammel net was composed of 3 layers, with the outer layers of the net (14–26 cm mesh size) covering the inner layer (4 cm mesh size).

After taking the box jellyfish out of the water, the whole tentacles from live jellyfish samples of both species were manually excised from the beachside and preserved in 1 M tri-sodium citrate solution (1 volume of tentacles: 9 volumes of citrate solution) at 4 °C. After that, the samples were transported to the lab, always kept at 4 °C, and frequently shaken for the cytolysis process.

For examining the distribution of cnidae, a centimeter of live jellyfish tentacle was excised and preserved in chilled glutaraldehyde solution for analysis with Light Microscopy (LM), Scanning Electron Microscopy (SEM), and Transmission Electron Microscopy (TEM).

For species identification, box jellyfish species were examined for morphological identification using photographs taken by a camera, bell height measuring, and branching pedalia counting. In addition, molecular identification was performed, including DNA extraction, PCR amplification, and sequencing, following the optimized protocol (Sathirapongsasuti et al., 2021). The resulting sequences were compared with the Thai box jellyfish database (https://med.mahidol.ac.th/transmed/en/Research/NS/Research/TBJ_Database) using the Basic Local Alignment Search Tool (BLAST) (http://bl-ast.Ncbi.nlm. nih.gov).

2.2 Nematocysts isolation and washing

The tentacle solutions (Figure 16A) were gentle rotation at 4 °C until less than 10-20 percent debris was observed under microscope. In this cytolysis period, the tentacles were frequently checked for % recovery of cnidae and then sieved through a 0.5-mm mesh size. (Figure 16B). Filtered solution (cnidae solution) was continually shaken. After approximately 90% recovery of cnidae, the solutions were sieved, and the filtered solutions were collected. Cnidae were kept using two different methods.

The first one, cnidae pellets were stored at -80 °C. Initially, the samples were centrifuged at 400 g at 4 °C for 20 min. Next, undischarged cnidae pellets were gently resuspended in chilled 1 M trisodium citrate solution at 1:20 (v:v) and separated them into 2 ml tubes. Afterward, the samples were washed twice with chilled 1 M trisodium citrate solution and centrifuged at 250 g for 20 min. The supernatant was removed, and the pellets were collected for morphological observation using the light microscope and then stored at -80 °C until use. (Figure 17)

In the second one, cnidae were maintained as cnidae solution (citrate solution) at 4 °C. The step started with two techniques of cnidae precipitation. In the first technique, the cnidae solutions were centrifuged at 4 °C at 400 g for 20 min. Undischarged cnidae pellets were resuspended in chilled 1 M tri-sodium citrate at 1:20 (v:v). The second technique, the cnidae solution, was continually precipitated at 1 g at 4 °C for a week. It would be separated into three layers (Figure 18). Then, each layer was collected into a separate tube for the cnidae pellets' checking before elimination. The precipitated pellets were resuspended in chilled 1 M tri-sodium citrate at a ratio of 1:20 (v:v). After the resuspension process from these two techniques of cnidae precipitation, the samples were given a gentle shake. Take 7 µl of samples to the Fast Read 102® plate for the quality control process by debris checking (debris refers to cytolyzed tentacle tissue). Next, the samples were washed at 250 g for 20 min, followed by debris checking and backwashing until the solutions ran clear or acceptable. During the process of the cytolysis method, the light microscope was used for the observation of nematocyst morphology.

Figure 16 (A) Tentacles from live jellyfish were preserved in chilled 1 M tri-sodium citrate solution at 4 °C. (B) The solutions were sieved through a 0.5-mm mesh size funnel filter. (Photographs by Chanikarn Yongstar)

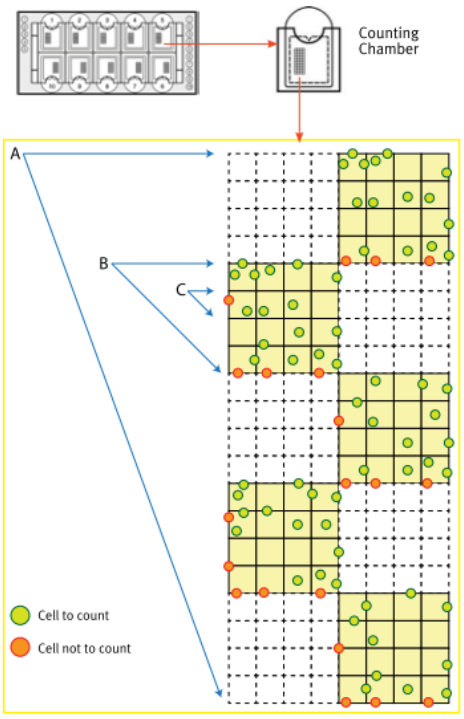

Figure 19 Fast Read 102 cell count: a disposable plastic device that is a slide divided into 10 independent chambers, each containing a standard volume of 7 µl. The sample was introduced into the chamber using a pipette and then examined the area of the grid under the light microscope. After the counting chamber was filled, the cells distributed in the 5 squares (black lines) were counted. Considering (A) each chamber contained a grid with a volume of 1 µl. (B) Each grid was divided into 10 squares. (C) Each square has a dimension of 1 x 1 mm, a depth of 0.1 mm, and a volume of 0.1 µl. Each square was subdivided into 16 smaller squares (called "sectors"). Considering the cells on the edges, it was only counted the upper and right sides of each square to avoid the risk of overestimation and underestimation.

2.2.1 Estimating the number of cnidae in a sample

The Fast Read 102® was used to count and estimate the number of cnidae present in the trisodium citrate solution (Figure 19). The amount of tissue debris and cnidocilia were counted and the cnidae concentration (cnidae/ml) was determined by the formula:

$$\text{Cnidae } \left(\frac{\text{cnidae}}{\text{ml}}\right) = \frac{\sum \text{cnidae counted in 5 square}}{5} \times 10^4$$

In counting, the types of cnidae were additionally classified based on the structure of the tubule, armature, and cnidae nomenclature with LM techniques according to Östman criteria. (Gershwin, 2006; Jouiaei, Casewell, et al., 2015; Östman, 2000).

2.2 Optimization of the conditions for maximum recovery of venom

This part aims to optimize the conditions for venom extraction from cnidae solutions. Preliminary tests with ultrasonication demonstrated in our hands its limited applicability to rupture the nematocyst cells. A lot of cnidae remained intact. I, therefore, explored in detail a bead mill homogenizer (Precellys 24 homogenizer, Bertin Technologies SAS, France). Moreover, different homogenization tubes with various beads in various sizes are available for this instrument. In this experiment, four types of homogenization tubes with various beads were used, including ceramic beads with a diameter of 1.4 mm, 2.8 mm, and a mix of 1.4 mm and 2.8 mm beads, as well as glass beads with a diameter of 0.5 mm. According to the manufacturer, tubes with ceramic beads with a diameter of 1.4 mm are recommended for soft animal tissue. Tubes with ceramic beads (2.8 mm in diameter) and mixed beads of both sizes are recommended for hard or vegetal tissues. They suggest that a mix of beads makes it possible to grind heterogeneous samples. The last type, glass beads with a diameter of 0.5 mm, is adapted for mechanical lysis of cells or bacteria. Besides the parameters of bead types, I also tried different three periods of homogenization intervals (40s,

45s, and 60s) and two levels of homogenization speed (5000 rpm and 6000 rpm). *C. buitendijki* samples were used for the first optimizing extraction method before going on to *C. indrasaksajiae* samples. According to estimating the number of cnidae in a sample, the proportion between cnidae and tissue debris is acceptable for extraction when the percentage of undischarged cnidae is greater than 60%.

2.3 Venom extraction

Prior to any process of extraction, a 7 µl sample (of each vial) of the fluid was placed on a Fast Read 102® cell counting slide to determine the number of whole cnidae in the solution. The extraction was performed one replicate due to the limitation of sample size with one sample. Approximately 750,000 cnidae for *C. indrasaksajiae* and 4 million cnidae for *C. buitendijki* were suitable amounts per extraction tube. This amount of cnidae was ~200 mg in wet weight. Then the amount of calculated chilled cnidae solution samples was transferred to chilled 2 ml homogenizing tubes containing various types of beads. These beads included ceramic beads with a diameter of 1.4 mm, 2.8 mm, and a mix of 1.4 mm and 2.8 mm beads, and glass beads with a diameter of 0.5 mm using a serological pipette. The samples were centrifuged at 4°C, 10,000g for 10 minutes. (Note: make sure that all cnidae were precipitate, not still suspended in solution.) After that, the supernatant was removed and discarded. For the extraction solvent, 2% SDS was used by adding up to 1.4 ml for each tube (the recommended maximum volume of homogenizing tubes). Cnidae pellets were resuspended by pipetting up and down gently. Then, the solutions in homogenizing tubes containing beads were shaken in Precellys 24 homogenizer at 5000 and 6500 rpm for 10-s , 15-s and 20-s intervals, repeat 4-6 cycles. (after 40 s approximately 95% of cnidae were ruptured for *Chironex* and 75% for *Chiropsalmus* (Carrette and Seymour, 2004)). Furthermore, the cnidae mixture was held in an ice bucket for two minutes before disruption started and for an additional one minute after each sequential disruption event. The percentage of discharged cnidae was monitored microscopically. Venom extracts were centrifuged at 10,000g at room temperature for 15 min to separate the protein dissolved in the solution. The supernatant was then aliquoted and immediately stored at -30 °C until use.

2.4 Quality control method

The Quality Control for samples includes measuring protein concentration and estimating per cent disruption. Firstly, the protein concentration was measured triplicate using a BCA protein assay kit. It was assumed that protein concentration was directly proportional to venom concentration (Carrette and Seymour, 2004). This BCA method was described by Smith et al. (1985). This study utilized albumin as a protein standard at concentrations of 0, 25, 125, 250, 500 to 1000 g/ml, and 1000 g/ml. The working reagent was prepared by mixing reagent A with reagent B (50:1). Then, the working reagent (200 µl) was mixed with the sample (25 µl) and incubated at 37 °C for 30 minutes. The peptide bond formed by the proteins can reduce Cu^{2+} in the working reagent to Cu^{+}, resulting in a change in the color of the solution from green to purple. The changing color can be measured using a microplate reader at 562 nm in Infinite M200 PRO microplate reader (Tecan, Grödig, Austria). The protein concentration of the sample can be calculated from protein standard curve. Another Quality Control process is calculating % disruption. The rest of sample at the bottom of each homogenized tube were taken 7 µl to the Fast Read chamber, then determined the number of wholes, and disrupted cnidae in the mixture using LM.

2.5 Statistic analysis

Due to the limitation of sample size with one sample, triplicate in this part were mentioned as replication of precision in each step of venom extraction. All results were expressed as means. The quantity of venom extracted from different conditions were evaluated by using compare means via SPSS software (version 24).

3. Results and discussion

3.1 Observations of cnidae

The cnidome, or census of cnidae in a species, was microscopically examined during cytolysis. In addition, induced discharge of cnidae was performed for explicit characterization. A total of 6 nematocyst types: large microbasic mastigophore, medium microbasic mastigophore, small microbasic mastigophore, trirhopaloid, small microbasic eurytele and ellipsoidal isorhiza, were identified in *C. indrasaksajiae* sample (Figure 20), whereas six nematocyst types: medium microbasic mastigophore, hockey-stick-form microbasic mastigophore, trirhopaloid, small microbasic eurytele, holotrichous isorhiza and ellipsoidal isorhiza, were observed in *C. buitendijki* (Figure 21). Interestingly, *C. buitendijki* and *C. indrasaksajiae* contained four main types of nematocysts: mastigophores, oval trirhopaloid, euryteles and isorhizas but there are some different in size, form, and proportion (Figure 22). Only holotrichous isorhiza and hockey-stick-form microbasic mastigophores were found in *C. buitendijki* but not *C. indrasaksajiae*.

The cnidae abundance was further examined as a percentage of the total count of each cnidae type. In *C. buitendijki* the proportion of mastigophores was less than that in *C. indrasaksajiae*. As a result of the proportion of euryteles and isorhizas, *C. buitendijki* had a higher proportion than *C. indrasaksajiae*. Finally, there is no difference in the proportion of oval trirhopaloid.

The proportions of these cnidae indicate the effect of box jellyfish species and medusa size on the proportion of cnidae. An increase in the proportion of mastigophores in the cnidome of *C. indrasaksajiae* may also be responsible for why *Chironex* species has caused numerous human fatalities, while the *Chiropsoides* species has not. McClounan and Seymour (2012) study showed that the proportion of mastigophore is presumably the lethal venom component. Similarly, the species and size of the medusae affected the proportion of euryteles and isorhizas that *C. buitendijki* had a higher proportion of euryteles and isorhizas than *C. indrasaksajiae*. According to Endean et al. (1969) and Carrette et al. (2002), the proportion of mastigophores in the genus *Chironex* increases rapidly from juvenile to mature. It

seems like the change in cnidae proportion of *Chironex* sp. fluctuates in response to its food. Moreover, an increase in the overall proportion of mastigophores indicates an increase in the amount of venom produced per animal required to paralyze or kill prey. Similarly, the variation in the proportions of euryteles and isorhizas emphasizes the hypothesis of changing cnidae proportions for different types of prey. According to the study by Rifkin and Endean (1983), the functions of isorhiza may be to grapple and hook to the surface of the prey by entanglement and adhesion. Moreover, this difference in the total proportion of mastigophores between *C. indrasaksajiae* and *C. buitendijki* could perhaps explain the differences in human fatalities related to both species. According to Williamson et al. (1996), mastigophores contain the venom associated with death. Thus, the proportion of mastigophores was formerly thought to be the reason for variation in fatal envenomation between these two species. The difference in fatalities encounters may be due to the percentage of mastigophores, with an increase in *C. indrasaksajiae* proving to be enough to give the lethal dosage as the results of several fatal cases in Thailand whereas *C. buitendijki* has not. (Fenner et al., 2010; PMBC Database, 2020; Sonthichai et al., 2016; Suntrarachun et al., 2001; Suriyan et al., 2019; Thaikruea and Siriarayapon, 2016; Thaikruea et al., 2012a; Thaikruea et al., 2012b)

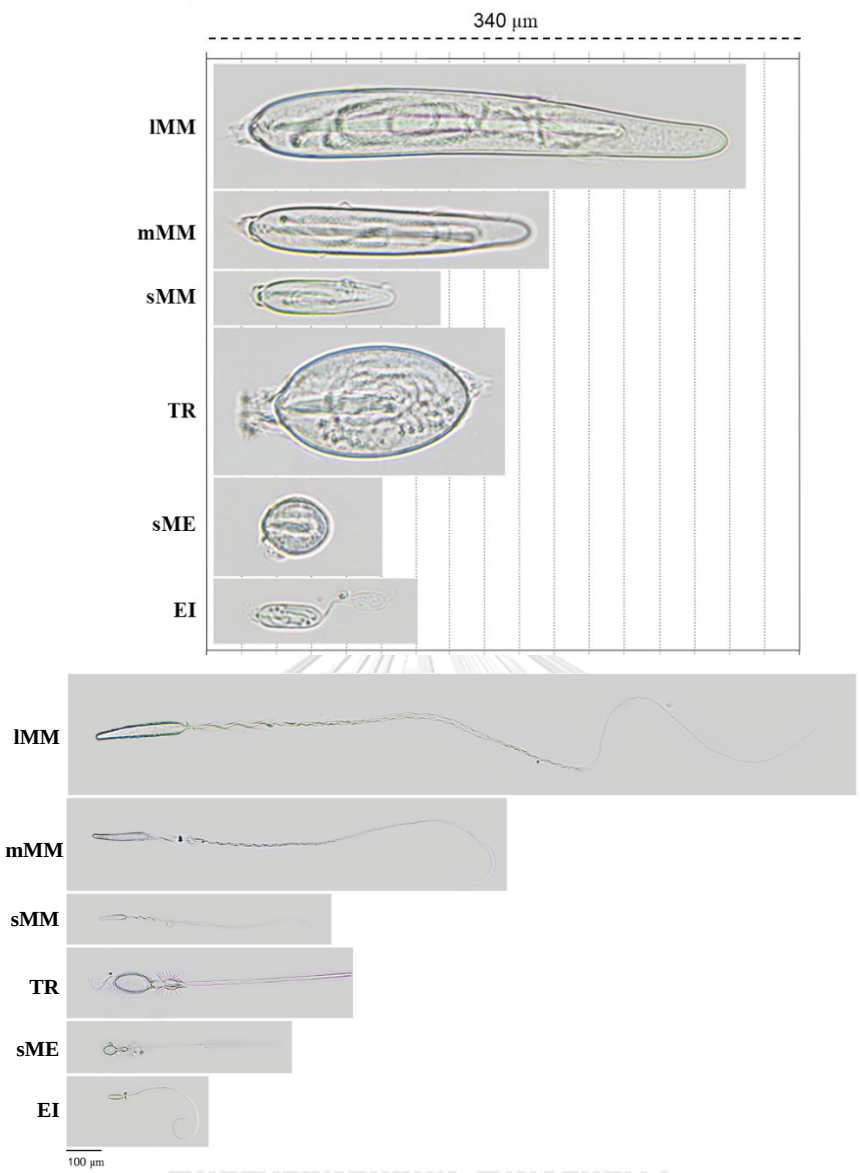

Figure 20 Representative undischarged and discharged cnidae of *C. indrasaksajiae*. Letters on left refer to the different types of undischarged cnidae, as follows: lMM = large microbasic mastigophore; mMM = medium microbasic mastigophore; sMM = small microbasic mastigophore; TR = trirhopaloid; sME = small microbasic eurytele; EI = ellipsoidal isorhiza. On the right side represent discharged cnidae; (A) discharged large microbasic mastigophore; (B) discharged medium microbasic mastigophore; (C) discharged small microbasic mastigophore; (D) discharged trirhopaloid; (E) discharged small microbasic eurytele; (F) discharged ellipsoidal isorhiza. Scale bars = 100 µm.

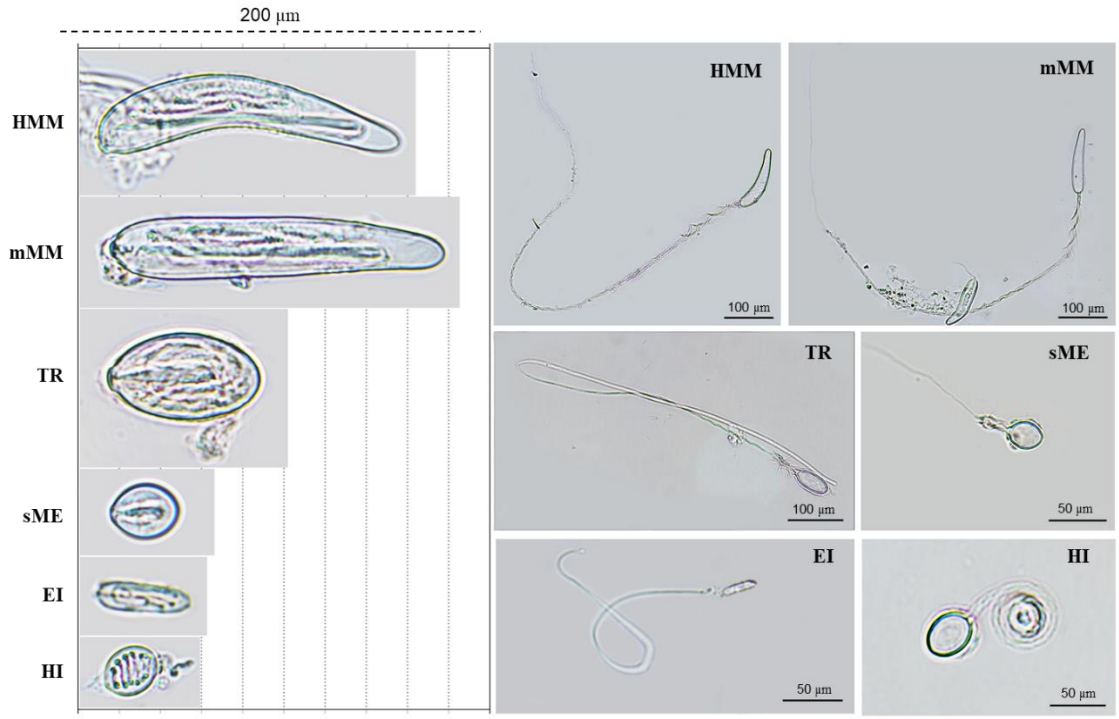

Figure 21 Representative undischarged and discharged cnidae of *C. buitendijki*. Letters on left refer to the different types of undischarged cnidae, as follows: mMM = medium microbasic mastigophore; HMM = hockey-stick-form microbasic mastigophore; TR = trirhopaloid; sME = small microbasic eurytele; HI = holotrichous isorhiza; EI = ellipsoidal isorhiza. On the right side represent discharged cnidae; (A) discharged medium microbasic mastigophore; (B) discharged banana-form microbasic mastigophore; (C) discharged trirhopaloid; (D) discharged small microbasic eurytele; (E) discharged holotrichous isorhiza; (F) discharged ellipsoidal isorhiza. Scale bars of HMM, mMM, TR = 100 µm and sME, EI, HI = 50 µm.

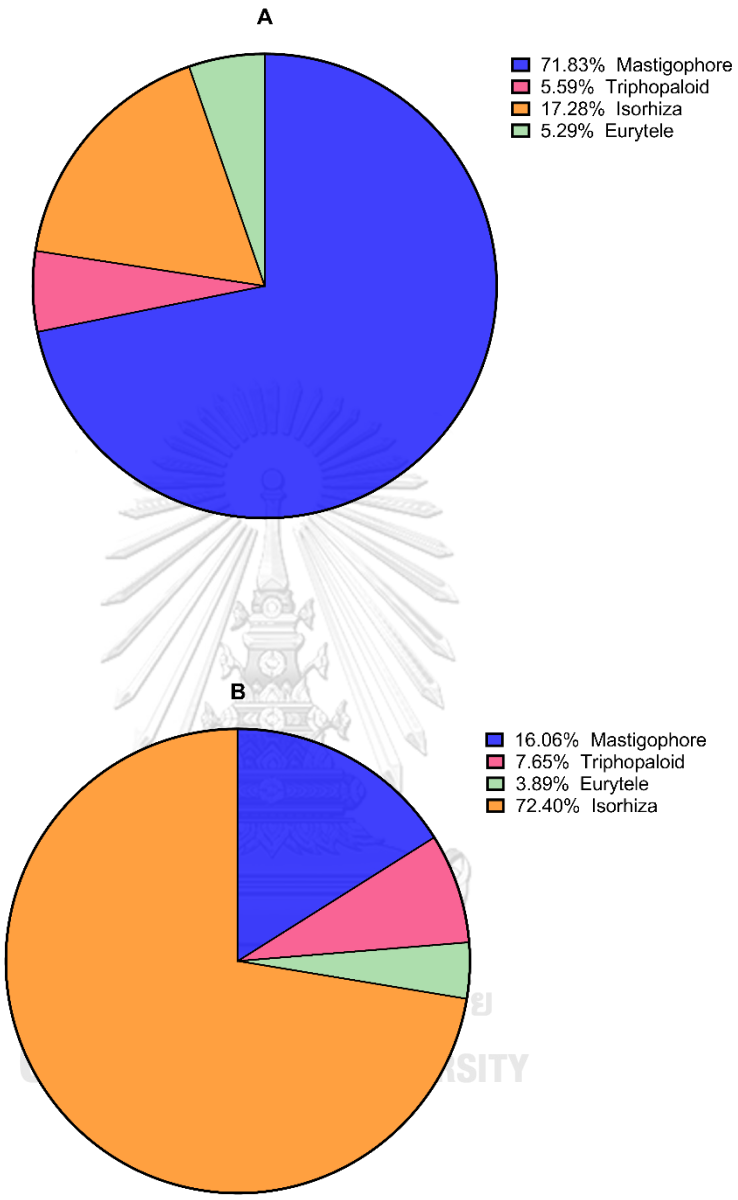

Figure 22 represents the proportion of multi-tentacle box jellyfish cnidae observed in (A) *C. buitendijki* and (B) *C. indrasaksajiae*. The pie chart represents the percentage of each type of cnidae in the cnidome present in each species.

3.2 Optimization of venom extraction using bead homogenization

This part aims to optimize the conditions of venom extraction from cnidae for maximum recovery of *C. indrasaksajiae* venom yields. The elucidation of the mechanism of action of these venoms has been hindered by several technological restrictions in venom preparation. Cnidarian envenomations here include the penetration of prey by myriad tiny, specialized penetrant cnidae, or nematocysts, each holding just picolitres of venom. Aqueous extract preparations of whole tentacles or partially purified cnidae provide only an incomplete proportion of aqueous soluble venom components that are contaminated with other tentacular and structural components, including cnidae capsule- wall collagens.

Cnidae extraction can be accomplished using several methods. Our preliminary tests with ultrasonication demonstrated the limited applicability of ultrasonication to rupture the nematocyst cells. The majority of the cnidae remained intact after ultrasonication. Therefore, one of the most commonly used methods for jellyfish venom extraction which is bead homogenization was considered to utilize in this process. Carrette and Seymour (2004) proposed that the method is quick, reproducible, and has little heat built up. In this study, I explored a Precellys 24 homogenizer by utilizing different types of bead homogenization tubes, different homogenization speeds, and different homogenization times. Experiments were first performed using *C. buitendijki* because the specimens were readily available with many samples for optimization and a greater quality of % cnidae recovery after the cytolysis process than with *C. indrasaksajiae* according to Yanagihara and Shohet (2012) procedure of venom preparation (Appendix figure A1-4). This is the newly developed method of osmotic effect on venom preparation. Trisodium citrate solution as strong as 1 M succeeded in obtaining a nice preparation of isolated cnidae by acting like a hypotonic solution for cnidae to lightly emission from cnidocyte without prompting the cnidae to discharge.

Step 1: Selection of beads; the results of the protein concentration and the percentage of cnidae disruption from the use of different types of beads with a setting homogenization speed of 5,000 rpm and a homogenization time of 40s based on the protocol of Carrette and Seymour (2004). This study clearly indicated that the

ceramic bead with a mix of 1.4 mm and 2.8 mm bead size is the most suitable for homogenizing cnidae (Table 3). According to the manufacturer, this bead is recommended for elastic tissue (Yu, 2016). Of these, it is proper for the cnidae that the first structural nematocyst molecules identified in isolated capsules were collagenous and termed (Beckmann and Özbek, 2012a).

Step 2: Selection of homogenized conditions; The highest quantity of protein concentration was obtained when the homogenization speed was set to 5000 rpm. and the homogenization time was set to 45 s (15 s-intervals with 3 cycles) (Table 4). The result showed the homogenization speed have effect on venom protein concentration. According to Carrette and Seymour (2004), increasing in speed of homogenization cause more heat buildup in tube lead to the possibility of venom denaturing. For the homogenization time, the highest quantity of protein concentration was obtained when the homogenization time was set to 45 s (15 s-intervals with 3 cycles) (Table 4). According to Carrette and Seymour (2004), after 40 s approximately 95% of nematocysts were ruptured for *Chironex* sp. and 75% for *Chiropsalmus* sp. The results of *Chiropsoides* revealed that increasing homogenization time increased yield. However, homogenizing for too long reduces yield because it allows more heat to accumulate during homogenization. It is another possibility of venom denaturing. Then, the homogenized tube with mixed size of ceramic beads were applied to homogenize at the condition of 5000 rpm in speed and 15 s intervals in time for *C. indrasaksajiae* venom extraction. However, the protein concentration and percentage of cnidae disruption results didn't turn out the way of expectation. Consequently, suitable conditions were then examined for this species. The most appropriate conditions for *C. indrasaksajiae* species were 0.05 mm glass beads with a homogenization speed of 5000 rpm and a homogenization time of 15 s–intervals.

Table 3 The average of protein concentrations released in cnidae disruption at homogenization speed of 5000 rpm and homogenization time of 40s for different types of beads.

	Protein concentration (µg/ml)	
Type of beads	Protein concentration (µg/ml)	% cnidae disruption
Glass beads (0.5 mm)	124.162	63.33
Ceramic beads (1.4 mm)	145.445	80.67
Ceramic beads (2.8 mm)	147.617	70.67
Ceramic beads (mixed of 1.4 mm, 2.8 mm)	159.113	85.00

Table 4 The average of protein concentrations obtained by different techniques of extracting venom from box jellyfish venom

	Protein concentration (µg/ml)	
Type of beads	*C. buitendijki*	*C. indrasaksajiae*
Glass beads (0.5 mm)	124.162	70.784

60s	187.021	-

Initial mass of cnidae 50 mg and *200 mg

CHAPTER IV

Venom proteome of the Thailand sea wasp, *Chironex indrasaksajiae* (cnidaria: cubozoa)

1. Introduction

A large number of humans experience jellyfish stings, particularly along with coastal areas of the ocean where numbered millions of stings take place annually worldwide (Fenner, 1997a). By stinging, many jellyfish species have been known to cause injuries or even death (Cegolon et al., 2013; Fenner and Williamson, 1996; Mubarak et al., 2021; Tibballs, 2006b). Such serious reactions which can be more than 100 fatal cases per year (Pirkle and Yanagihara, 2019), are consequences of stings inflicted by box jellyfish which the infamous *Chironex fleckeri* (Australian box jellyfish) is considered as one of the most venomous marine creatures in the world (Williamson et al., 1996). A meter of tentacle contact can occasionally result in death attributed to acute cardiovascular collapse within minutes after stinging (Yanagihara and Shohet, 2012).

Thailand is located in the Indo-Pacific region, the hotspot zone for box jellyfish envenomation (Gershwin et al., 2010; Gershwin et al., 2013). The medical records showed numerous envenomation cases of box jellyfish (both Thai and foreigners) in Thai water since 1998 (Thaikruea and Siriarayapon, 2014). However, many people do not believe that box jellyfish can kill humans, so they dismiss and neglect this problem. Thus, the knowledge about box jellyfish biodiversity or envenomation has been limited in Thailand. Currently, twelve species of jellyfish in Class Cubozoa are found in Thai waters (PMBC Database, 2020; Toshino et al., 2019). Among all species found in Thai waters, Chirodropids, or multi-tentacled box jellyfish, are believed to pose a serious danger to humans which have been referred from the injuries and fatal case reports of box jellyfish envenomation in Thailand (Thaikruea and Siriarayapon, 2015b, 2016, 2018; Thaikruea et al., 2012a; Thaikruea et al., 2012b). Until now, regarding the animal distribution and seasonal, *C. indrasaksajiae* is expected to be a cause of seven fatal cases in the central Gulf of Thailand, the islands of Samui and Pha-ngan (Thaikruea and Siriarayapon, 2016).

This species has recently been described as a new species of box jellyfish from the Gulf of Thailand (Sucharitakul et al., 2017). The envenomation of the genus *Chironex* occasionally results in death attributed to acute cardiovascular collapse within minutes (Tibballs, 2006b).

The entire tentacle and nematocyst extracts of *Chironex* have been linked to several biological activities, including fatal, dermonecrotic, nociceptive, cytotoxic, neurotoxic, myotoxic, and cardiotoxic effects (Brinkman and Burnell, 2009). Even though *C. indrasaksajiae* venoms have a significant medical and pharmacological impact on humans owing to the high number of fatalities in Thai water and because it is a newly described species in Thailand; thus, their compositions have not yet been studied. This is the first time that the proteomic characterization of the venom of *C. indrasaksajiae* has been done. This may be valuable information in understanding the venom compositions and their modes of action and also helpful for treating stung patients.

2. Materials and methods

2.1. Jellyfish collection

The animal collection was done according to the approved protocol, Mahidol University-Institute Animal Care and Use Committee, and Mahidol University Biosafety Committee. *C. indrasaksajiae* was captured near the coastal zone at Chaloklum bay of Koh Pha-ngan (Suratthani, the Gulf of Thailand) in August 2019. Whole tentacles from live jellyfish samples of these two species were manually excised and preserved in 1 M tri-sodium citrate solution (1 volume of tentacles: 9 volumes of citrate solution) and kept at 4 °C, then vigorously shaken for the cytolysis process.

For species identification, box jellyfish species were examined for morphological identification using photographs taken by a camera, bell height measuring, and branching pedalia counting. In addition, molecular identification was performed, including DNA extraction, PCR amplification, and sequencing, following the optimized protocol (Sathirapongsasuti et al., 2021). The resulting sequences were

compared with our Thai box jellyfish database (https://med.mahidol.ac.th/transmed-/en/Research/NS/Research /TBJ_Database) using the Basic Local Alignment Search Tool (BLAST) (http://blast.ncbi.nlm. nih.gov).

2.2 Venom extraction for *Chironex indrasaksajiae*

Box jellyfish venom was extracted using a bead mill homogenizer (Precellys 24 homogenizer, Bertin Technologies SAS, France) according to the manufacturer's protocol and the method described by Carrette and Seymour (2004) with some modifications. Briefly, 200 mg of cnidae (approximately 750,000 cnidae of *C. indrasaksajiae*) were aliquoted to a Precellys 24 VK05 lysing kit 2.0-ml tube with 0.5 mm glass beads and 1.4 ml of 2% SDS were then added to the tube. Samples were processed in 6 cycles, each consisting of a bead beating at 5,000 rpm for 15 seconds. Tubes were rested on ice for at least 1 minute between each cycle. Lysates of venom extract were cleared by centrifugation at 10,000g at 4°C for 15 minutes. Supernatants were aliquoted to a protein LoBind 1.5 ml tubes and stored at -30°C until used. The percentage of discharged cnidae was monitored microscopically.

BCA protein assay was used to measure protein concentration. It was assumed that protein concentration was correlated with venom concentration (Carrette and Seymour, 2004). Measurement of protein using bicinchoninic acid was described by Smith et al. (1985). Albumin was used for protein standards at concentrations of 0, 25, 125, 250, 500, 750, 1000, 1500 and 2000 µg/ml. The samples were read at 562 nm in Infinite M200 PRO microplate reader (Tecan, Grödig, Austria). Prior to the venom activity assay, frozen venom samples were thawed and are referred to as "thawed" venom.

2.3 SDS-PAGE

The venom proteins from box jellyfish cnidae were separated by Sodium Dodecyl Sulfate polyacrylamide gel electrophoresis (SDS-PAGE) to separate proteins according to their sizes and charges. Twenty microliters of venom solutions were prepared, consisting of the sample (13 µl), loading buffer (5 µl), and 100 mM

DTT (2 µl). The solution was then heated at 95 °C for 3 minutes, followed by a 30-second spin-down step. Next, the venom solutions were loaded into a Run-Blue™ 4–12% bis-tris precast gel (Expedeon, San Diego, CA, USA). The gel was placed in a RunBlue MES buffer system and ran at a constant voltage of 100 V for 45 minutes. After protein separation, protein bands were visualized using InstantBlue® protein stain for 2 hours, and the size of protein bands was compared with the protein marker (Enzmart Biotech, Bangkok, Thailand).

2.4 In-gel tryptic digestion

The protein bands were excised from a gel into small pieces (5 fragments) and placed in Eppendorf tubes for in-gel digestion following the protocol from Shevchenko et al. (2006) with modifications. Gel fragments were destained using 500 µl of 100 mM ammonium bicarbonate and acetonitrile (1:1 vol/vol), incubated and vortexed for 30 minutes. After 30 minutes, the solution was removed, and acetonitrile (200 µl) was added to shrink the gel. The protein in the gel was then reduced with 10 mM DTT (200 l) and incubated for 30 minutes at 56 °C. After that, acetonitrile (200 µl) was added after 10 minutes of incubation. Then 55 mM chloroacetamide solution (200 µl) was added to alkylate the proteins and incubated for 20 minutes in the dark. The gels were shrunk with acetonitrile solution for about 10 minutes. 13 ng/µl of trypsin (150 µl) were added to the gel pieces and incubated on ice for 120 minutes to saturate the gel. Then the trypsin solution was removed before adding 100 mM ammonium bicarbonate (100 µl) to cover the gel pieces. The proteins were then digested and incubated overnight at 37 °C. After that, peptides were extracted by extraction buffer (5% formic acid and acetonitrile, 1:2 vol/vol) and incubated at 37 °C for 15 minutes. Then peptide solution was collected and lyophilized by the evaporator. Then, peptides were resuspended with 100 µl of 0.1% formic acid for LC-MS/MS analysis.

2.5 Peptides preparation for LC-MS/MS analysis

Prior to LCMS/MS analysis, the peptide samples were desalted using C_{18} StageTips (Rappsilber et al., 2007). Briefly, microcolumns for peptide desalting were prepared from 200-µL pipette tips and a C_{18} membrane disk. Two mg/mL of Jupiter® C_{18} beads (15 µm, Phenomenex, Torrance, CA, USA) suspended in acetonitrile was packed on the C_{18} membrane disk by centrifugation at 3000g for 3 minutes. The spin column was equilibrated with 0.1% formic acid, and the peptide samples were applied to the sorbent. Bound peptides were washed with 0.1% formic acid and eluted by 0.1% formic acid in 70% acetonitrile. The solvent was evaporated using vacuum centrifugation, and dried peptides were stored till LC-MS/MS analysis at –80°C.

The venom peptides samples were resuspended in 0.1% formic acid. They were then subjected to a Pierce™ peptide quantification assay using fluorescence detection following the protocol suggested by the manufacturer for venom peptide quantification. Briefly, albumin peptides were used as the standard solution at concentration of 0, 7.8, 15.6, 31.3, 62.5, 125, 250, 500 and 1000 µg/ml. The standard and sample solutions (10 µl) were incubated with 70 µl of fluorometric peptide assay buffer and 20 µl of fluorometric peptide assay reagent for 5 minutes. The fluorescence of sample was measured at the excitation wavelength of 390 nm and emission wavelength of 475 nm using a fluorescence spectrophotometer (Agilent Cary Eclipse fluorescence spectrophotometer, Agilent).

2.6 LC-MS/MS analysis

Dried venom peptides were resuspended in 0.1% formic acid. Each 400 ng of the resuspended peptides was injected into a C18 analytical column for low-pH reverse phase separation using an Acclaim™ PepMep™ 100, nanoViper C18 column (75 µm × 2 cm, 3 µm, Thermo Fisher Scientific) coupled to an EASY-nLC 1000 ultra-high pressure liquid chromatography system (Thermo Fisher Scientific). Peptides were separated by a gradient concentration mixture of mobile phase buffer (solvent A: 0.1% formic acid and 99% Type I distilled water) and eluting buffer

(solvent B: 0.1% formic acid and 99.9% acetonitrile) shown in table 5. The solvent A and B were run over 60 min at a flow rate of 300 nL/min. After separation, eluted peptides from the column were ionized by nano-electrospray ionization before being transmitted to the mass spectrometer. The Easy-nLC 1000 was connected online with a Q Exactive Hybrid Quadrupole Orbitrap mass spectrometer (Thermo Fisher Scientific) using an EASY-Spray ion source (Thermo Fisher Scientific) as an interface. The ions spray voltage was set to 2000 V. The mass spectrometer was operated in the Data Dependent Acquisition (DDA) mode in which a full MS scan (the mass range of precursor ions: 350-1600 m/z; the resolution of orbitrap mass analyzer: 70,000; the precursor AGC: $3x10^6$) was followed by the 10 most intense precursor ions being subjected to Higher-energy Collisional Dissociation (HCD) fragmentation. The precursor ions with a charge of > +1 were selected for fragmentation. HCD fragmentation was performed and acquired the automatic gain control (AGC) target of $5x10^4$, maximum injection time of 100 milliseconds and an isolation window of 2.0 m/z. The m/z of product ions was scanned at a resolution of 17,500. All data were acquired using Thermo Xcalibur 2.2 software (Thermo Fisher Scientific).

Table 5 Concentration of mobile phase buffer (solvent A) and eluting buffer (solvent B) were used to elute peptides for 60 minutes.

Time (minutes)	% Solvent A	% Solvent B
0	95	5
43	80	20
53	60	40
55	5	95
60	5	95

2.7 Spectral searches and bioinformatics analysis

The raw MS/MS spectral data from each LC-MS/MS run was searched against the custom cnidarian proteins and toxins databases using MaxQuant software (Galaxy Version 1.6.10.43) with the Andromeda search engine in the Galaxy bioinformatics platform (Cox et al., 2011; Tyanova et al., 2016). Default settings were used, with "match between runs", "iBAQ (intensity-based absolute-protein-quantification)" and "PTXQC (proteomics quality control of MaxQuant search)" turned on. For protein identification, a minimum peptide length of 7 amino acids was required. The peptide and protein false-discovery rate was set at 1%. Enzyme specificity was set to trypsin, allowing 2 missed cleavages. For the first peptide identification search, the mass tolerance was 20 ppm. After time and mass-dependent peptide mass recalibration, a peptide mass tolerance in the main search of 4.5 ppm was used. For the MS/MS, a fragment mass tolerance was set to FTMS 20 ppm, and ITMS 0.5 Da. For all searches, cysteine carbamidomethylation was set as a fixed modification and oxidation of methionine and N-terminal acetylation as variable modifications. The quality of the generated results by MaxQuant was further verified by the PTXQC option in the Galaxy platform (Bielow et al., 2016). For protein quantification, the iBAQ value, where the sum over all the peptides of a protein is divided by the number of theoretically observable peptides, was used to estimate an approximate measure of absolute protein abundance (Schwanhäusser et al., 2011; Tyanova et al., 2016). Then, the proteins were assigned to different protein groups, and the percentage of each protein group was calculated by dividing the summed iBAQ values of proteins assigned to the group by the summed iBAQ values of all quantified proteins identified in the sample.

Spectral data were searched against four databases: 1) a custom database created from UniProtKB/Swiss-Prot entries retrieved from separated taxonomy searches for "Cnidarian" (263,816 entries), 2) a custom database created from UniProtKB/Swiss-Prot entries retrieved from separate keyword searches for "toxin", "venom", "hemolysin" or "porin" (191,347 entries), 3) a custom database created from entries retrieved from the annotated Tox-Prot program (https://www.uniprot.org/pro-gram/Toxins; 7,437 entries) (Jungo et al., 2012), and 4)

a custom database created from GenBank (NCBI) entries retrieved from separated keyword searches for “hemolysin” or “hemolysis” or “pore-forming protein” or “porins” (156,104 entries).

Perseus version 1.6.15.0 (available online at https://maxquant.net/perseus/) was used for MS/MS data processing and visualization. Many protein IDs can be allocated to the same protein groups because a single peptide might be linked to multiple proteins (such as in the case of razor proteins). In order to avoid redundant proteins in analysis while still maintaining the maximum information, a leading protein-based protein identification technique was introduced. In brief, an initial table was constructed that contained the protein group information. Leading proteins and majority proteins were combined after the proteins tagged (+) with "only identified by site," "reverse," and "contaminant" were excluded from the initial table. The final table was improved by correcting the leading protein sequences, removing the comprehensive contaminants, and recalculating the sequence length and iBAQ. The proteins (leading and majority) were annotated with the molecular functions and biological process of identified proteins using the batch retrieval tool on the PIR database (https://proteininformation-resource.org/) (Ashburner et al., 2000; Wu et al., 2003). All peptide contig sequences of potential box jellyfish toxin families, which were retrieved from the identified proteins in "protein groups.txt", were manually constructed for each toxin by mapping the start and stop positions on the reference sequence. Multiple Sequence Alignment was performed using Clustal Omega (Madeira et al., 2019) and visualized using Jalview software (Waterhouse et al., 2009). Sequence similarity of proteins was analyzed by EMBOSS Needle (Madeira et al., 2019). A full table of mass spectrometric and database search features for each identified protein (accession numbers, sequences, Gene Ontology (GO) annotations, and InterPro results) can be found in Appendix: Dataset 1. Additionally, all peptides that were identified by MaxQuant in “peptide.txt” were tabulated, with duplicate sequences removed, keeping only the highest scoring peptide among the duplicates. All peptides scoring “NaN” (not a number) were also removed. GO annotations of all sequences from these filtered peptides were done by eggNOG-mapper using the default setting. For quantitative data and graphs were performed using the software

GraphPad Prism (version 8). The area proportional Venn diagrams were obtained using the freely available online tool BioVenn (Hulsen et al., 2008).

3. Results and discussion

3.1 Venom profiling

The sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) pattern of *C. indrasaksajiae* venom proteins is shown in figure 23. The molecular weights of proteins varied from <20 kDa to 200 kDa. The *C. indrasaksajiae* venoms contained only one condensed protein band at approximately 50 kDa and two minor protein bands at about 60 kDa and 150 kDa.

After decades of research on the proteins in box jellyfish venom, several studies have shown that the SDS-PAGE profiles of nematocyst venom or tentacle extracts are dominated by one or two major proteins with similar molecular weights (42–46 kDa) (Brinkman and Burnell, 2008; Brinkman and Burnell, 2007, 2009; Nagai, Takuwa, et al., 2000a; Nagai, Takuwa, Nakao, Sakamoto, et al., 2000; Wiltshire et al., 2000). There is no significant amino acid sequence homology between the box jellyfish toxins and other known proteins, suggesting that the toxins belong to a unique family of bioactive proteins (Brinkman and Burnell, 2007; Nagai et al., 2002). Toxins produced by box jellyfish are typically labile, basic proteins with molecular weights ranging from 42 to 46 kDa capable of producing severe hemolytic activity. The results of bioactivity assays for selected toxins also indicate that the proteins are lethal and induce localized pain, inflammation, and dermonecrosis (Nagai, Takuwa, et al., 2000a; Nagai et al., 2002; Nagai, Takuwa, Nakao, Sakamoto, et al., 2000). According to secondary structural studies and remote protein homology predictions, the box jellyfish venom may act as a pore-forming toxin (Parker and Feil, 2005). However, major protein bands of *C. indrasaksajiae* venoms had a molecular weight of between 47 and 57 kDa, which is a larger size than a novel family of bioactive box jellyfish venom proteins (Table 6). In addition, our LC-MS/MS observation showed that major protein bands of *C. indrasaksajiae* venoms could have resulted from a pore-forming toxin, porins, hemolysin, and basic cytolysins.

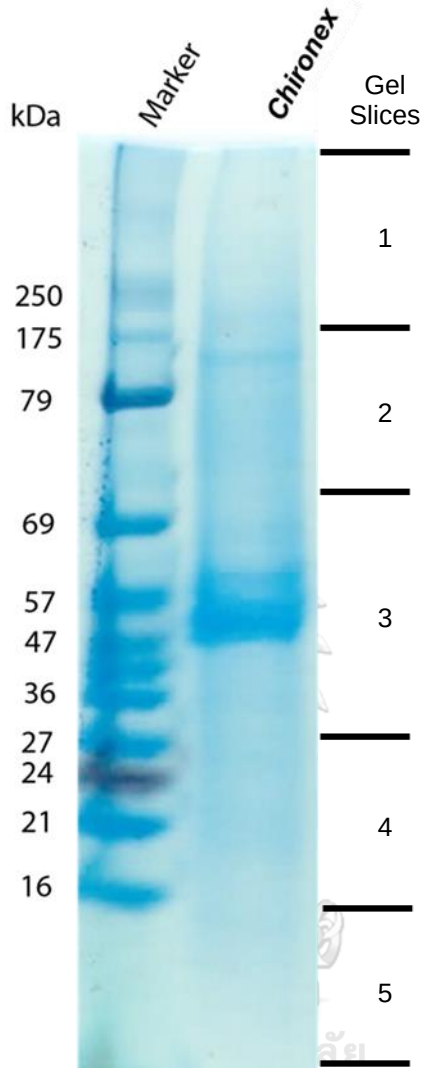

Figure 23 Gel electrophoresis profile of venom proteins from *C. indrasaksajiae* venom sample, using 4-12% Bis-Tris gel. Sizes of 5 gel slices for the in-gel digestion experiment were indicated on the right.

Table 6 Comparison *C. indrasaksajiae* venom proteins from novel family of bioactive box jellyfish proteins

3.2 Proteomic analysis of *C. indrasaksajiae* venom

3.2.1 Overall composition of peptide and protein identification from *C. indrasaksajiae* cnidae venom

To identify proteins in *C. indrasaksajiae* venom, crude venom was fractionated using SDS-PAGE and peptides from in-gel tryptic digests of 5 gel fragments (Figure 23) were analyzed using liquid chromatography with tandem mass spectrometry (LC-MS/MS). For screening proteins in *C. indrasaksajiae* venom, the spectral data were searched against all Cnidarian entries presented in the Swiss-Prot database with the significance threshold set as P-value < 0.05 to ensure the exclusive inclusion of the statistically significant protein matches as described in section 2.7. Any contaminants or false positive hits were removed during this filtering process. As the results of protein identification based on an MS/MS ion search with 3.9 % MS/MS identified, a total of 532 unique protein groups and a total of 1,241 unique peptides were identified from in-gel digestion experiment (Appendix: Dataset A1). Based on functional annotation, identifications included proteins associated with cellular and metabolic processes, structural components, and potential toxins. Uncharacterized and predicted proteins were excluded for de novo sequencing in further analysis due to not having been annotated in the PIR database.

The most commonly identified proteins were structural from the annotated proteins, reflecting the composition of the cnidae capsule, primarily

composed of minicollagens (Özbek et al., 2009), and the tubule in which tubulin is a major component. Molecular components of the nematocyst capsule body is primarily composed of minicollagens (Özbek et al., 2009), and the actin and tubulin are major components in the tubule, spines, as well as proteins associated with cnidocilia of nematocyte (Beckmann and Özbek, 2012a) that were incomplete cytolyzed in venom preparation process. A detection of identified structural proteins in *C. indrasaksajiae* venom, including actin, tubulin beta chain, tubulin alpha chain etc., have a similar result in the nematocyst proteomes of *C. fleckeri* in which non-secreted proteins were hypothesized to play an important role in nematogenesis, to be products of unusual secretion pathways or truncated protein products (Brinkman et al., 2012).

When categorized into functional groupings, the most abundantly identified proteins reflect the known composition of the cnidae, with toxins, collagens, and proteins that play important roles in basal metabolisms such as actin, tubulin, histones and ATPase (Figure 24, Table 7). Other categorized protein groups were the cytoskeleton components, membrane-bound enzyme, mitochondrial gene products, muscular and non-muscular components, photoprotein, a signaling protein, heat shock protein, transcription and translation factors, ATP-binding protein, enzymes and cellular oxido-reductive proteins. All of these proteins resemble the jellyfish in the class Scyphozoa, Cubozoa, Hydrozoa, Ctenophores, and most of them are similar to the proteins derived from the same genus in the venom proteomes *C. fleckeri* (Brinkman et al., 2012).

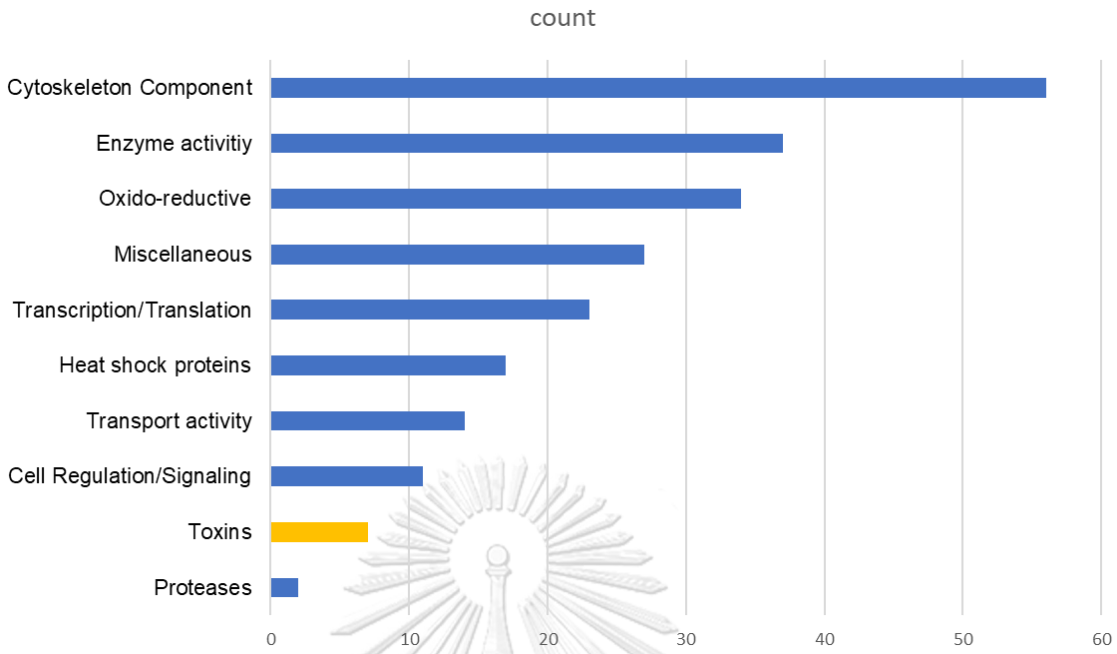

Figure 24 Venom proteome of *C. indrasaksajiae*: Functional annotation of proteins identified in proteomics experiments.

Table 7 Protein identification is categorized into functional groupings using MAXQUANT and ANDROMADA

Table 8 showed that the most abundant peptides making the top six hit list were matched with *C. fleckeri* toxin-1 (CfTX-1) and toxin-2 (CfTX-2). These abundant peptides reflect the amount of toxin in *C. indrasaksajiae* cnidae venom, suggesting these toxins play an important functional role in box jellyfish envenomation. CfTX-1 and CfTX-2 were also the major toxin protein components in *C. fleckeri* venom with molecular masses ~43 and 45 kDa, respectively (Brinkman, 2008; Brinkman et al., 2012; Brinkman and Burnell, 2008; Brinkman and Burnell, 2007, 2009; Brinkman et al., 2015).

In the screening for toxins in the cnidarian database, the results of toxin protein identification in *C. indrasaksajiae* venom, only 7 toxin proteins were found. (Appendix: dataset 2) Due to the limited number of annotated toxin proteins available in the cnidarian database used for the search, the cnidarian database provided 304 toxin proteins, but only 8 of those toxin proteins were annotated in the box jellyfish group. To maximize toxin identifications, spectral data were also compared against other publicly available toxin databases as noted in Section 2.7 from Tox-Prot program and custom databases with keyword searched for “toxin” or “venom” or “hemolysin” or “hemolysis” or “pore-forming protein” or “porins”. The protein matches from all custom toxin database searches were pooled together for qualitative analysis, resulting in the identification of 74 potential toxin groups (Table 9). The vast majority of them such as Jellyfish toxin family (JFTs) (Klompen et al., 2021), pore-forming protein (PFTs) (Mesa-Galloso et al., 2021; Parker and Feil, 2005; Podobnik and Anderluh, 2017), porin family (Jeanteur et al., 1994; Sardiello et al., 2003; Yanagihara and Shohet, 2012) and hemolysin (Chung et al., 2001; Crone and Keen, 1969) contained the toxins that contributed to hemolysis (Figure 25). Hemolytic toxic effects that the destruction of red blood cells by pore-forming protein or porin might be suspected as the fatal mechanism of box jellyfish envenomation (Mesa-Galloso et al., 2021; Yanagihara and Shohet, 2012; Yanagihara, Wilcox, Smith, et al., 2016). Other toxins were also detected in venom proteome of *C. indrasaksajiae*, comprising the toxic components including hemostasis impairing toxin, oxidoreductase, enzyme (hydrolase, protease), metalloproteinase, signaling protein, cytolytic toxin, neurotoxin and miscellaneous (Brain-derived neurotrophic factor). This pattern of toxin family distribution is similar to the venom proteomes of

other medusozoans, including *C. fleckeri* (Brinkman et al., 2012), in which the most abundant venom proteins identified were pore-forming toxins.

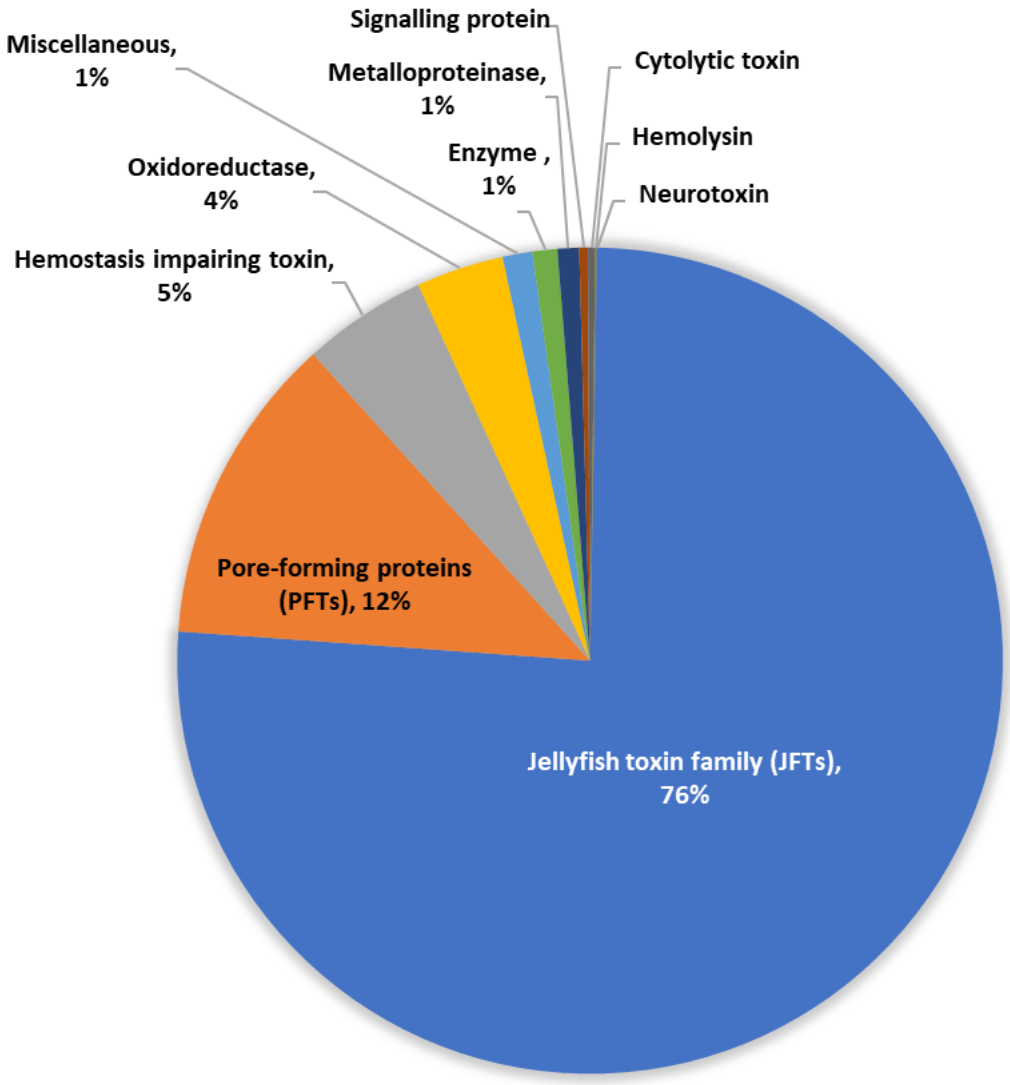

Figure 25 Abundance of each protein family estimated by iBAQ values:

3.2.2 Potential toxin proteins identified in the *C. indrasaksajiae* venom proteome

As the results of toxin protein identification in *C. indrasaksajiae* venom that were searched against Tox-Prot program and custom toxin databases in table 9, it showed that the most abundant protein making the top hit list were matched with *C. fleckeri* toxin-1 (CfTX-1) and toxin-2 (CfTX-2) which accounted for 50% and 16% of the total toxin protein content, respectively. These highly abundant venom proteins belong to a family of taxonomically restricted novel cnidarian toxins (42– 46 kDa) that includes CqTX-A, CrTX-A, and CaTX-A from box jellyfish species *Chironex yamaguchii* (Nagai et al., 2002) (as *Chiropsalmus quadrigatus* (Lewis and Bentlage, 2009)), *Carybdea rastonii* (Nagai, Takuwa, et al., 2000a), and *Alatina moseri* (Nagai, Takuwa, Nakao, Sakamoto, et al., 2000) (as *Carybdea alata* (Gershwin, 2005a)), respectively, as well as other representatives from Cubozoa, Scyphozoa, and Hydrozoa. Recently, proteins with sequence homology to the box jellyfish toxins have also been identified in the venoms of Scyphozoa, such as *Cassiopea xamachana* (Ames, 2016), *Cyanea capillata* (Lassen et al., 2011), *Nemopilema nomurai* (Li et al., 2020), *Chrysaora fuscescens* (Ponce et al., 2016) and the hydrozoan *Hydra magnipapillata* (Balasubramanian et al., 2012), inferring the toxin family is present throughout Cnidaria. Members of this toxin family are potently hemolytic and cause pain, inflammation, dermonecrosis and death in experimental animals (Hornbeak and Auerbach, 2017; Tibballs, 2018; Tiemensma et al., 2021; Yanagihara, Wilcox, Smith, et al., 2016), suggesting the toxins play an important functional role in jellyfish envenoming. In cubozoans, computational analyses of this toxin family have been linked to the presence of a specific family of porin family or pore forming toxins (PFTs), described as the most potent cnidarian toxin families currently known (D'Ambra and Lauritano, 2020; Jayathilake and Gunathilake, 2020; Jouiaei, Yanagihara, et al., 2015; Podobnik and Anderluh, 2017). The apparent restriction of a cnidarian-specific PFT family to medusozoan venoms resulted in the current nomenclature of “jellyfish toxins (JFTs)” (Jouiaei, Yanagihara, et al., 2015; Klompen et al., 2021; Surm and Moran, 2021).

Putative pore-forming toxins were the second most abundant toxin group, accounting for 12% of the total toxin protein content. Using a combined database, there were 9 PFTs proteins identified, comprising polycystic kidney disease protein 1-like 2, type II secretion outer membrane pore-forming protein (PulD), alpha-xenorhabdolysin family binary toxin subunit B, colicin-like pore-forming protein, pore-forming outer membrane protein, protein CyaE, thrombospondin type 3 repeat-containing protein, toxin CdiA and porin family.

Full amino acid sequence analysis and molecular modelling, show that the porin has structural motifs familiar with self-assembling bacterial porins, such as anthrolysin O and streptolysin O (Bernheimer et al., 1979). Afterwards, Chung et al. (2001) reported on the first hemolytic porin from *Alatina* sp. (previously reported as *Carybdea alata*). Since then, all cubozoan venom has been found to have close homologous proteins. In *C. fleckeri* venom, there are 2 different isoforms of this porin (MW 43 and 45 kDa) (Brinkman and Burnell, 2009; Nagai, Takuwa, Nakao, Sakamoto, et al., 2000; Yanagihara, Kuroiwa, Oliver, Chung, et al., 2002). Moreover, secondary structure analysis and remote protein homology predictions suggest that the family of box jellyfish toxins (CfTXs, CqTX, CrTX and CaTX) may act as α-PFTs, with three-domain Cry-like toxins. These domains were estimated that might play an essential role in membrane penetration and pore-forming after binding to the specific receptors (Brinkman and Burnell, 2009; Podobnik and Anderluh, 2017). Thus, the fact that porins are conserved across all cnidarian species supports the concept that these proteins are key venom components and play an important role in the clinical symptoms of cubozoan stings (Yanagihara, Wilcox, Smith, et al., 2016).

According to Yanagihara's theory, the venom of box jellyfish contains proteins that break down red blood cells and allow potassium to be released. The efflux of K^+ causes the electrical rhythms that keep the heart pumping to be disrupted and the heart to stop beating. Not only ion channel blockers in venom but also many “porins”: proteins that puncture cells, allowing their contents to leak out. In 2012, Yanagihara and a colleague reported that the venom of *Chironex fleckeri* rapidly punctures red blood cells, causing them to leak a huge amount of potassium ions. A high level of potassium in the blood, or hyperkalemia, causes cardiac arrest,

and when the mice were injected with high doses of venom, their hearts quickly stopped. The same happened when the mice were injected only the porins from the venom that porins were suspected might be the lethal components by destroying red blood cells.

In the venoms, metalloproteases were the predominant protease enzymes. Mainly, they were homologous to zinc metalloproteinase-disintegrin and metalloproteinase domain-containing protein, which were also identified in the proteome of the venom of other cnidarians, including Lion's mane jellyfish *C. capillata*, sea wasp *C. fleckeri*, Pacific sea nettle *C. fuscescens*, ghost jellyfish *Cyanea nozakii*, *Cyanea sp.*, Nomura's jellyfish *N. nomurai*, cannonball jellyfish *S. Meleagris* , and starlet sea anemone *Nematostella vectensis* (Leung et al., 2020). It has been suggested that metalloprotease induces protease-mediated tissue damage by the degradation of the extracellular matrix, which eventually results in necrosis, oedema, and haemorrhage (H. Lee et al., 2011). Correspondingly, the skin and tissue necrosis caused by *C. indrasaksajiae* envenomation (Tibballs, 2018) is most likely associated with the highly represented metalloproteases in its venom. However, the functional role of proteases in jellyfish venom is not well understood. At the same time, based on observations in other venomous animals, the results suggested that the proteases in the venom may be responsible for promoting the spreading and activation of other toxins.

Jellyfishes are exposed to continuous environmental changes, such as salinity, temperature, pollution, solar radiation, microorganisms and pathogens. This can cause the activation of inner defence responses, namely the production of reactive oxygen species (ROS). Although ROS are needed in the organism, an excess of these chemical species could cause a metabolic balance disorder, damaging cellular lipids, proteins and DNA. Catalase, glutathione peroxidase, superoxide dismutase, thioredoxin and peroxiredoxins are proteins with powerful antioxidant properties. *C. indrasaksajiae* showed to possess peroxiredoxin. These antioxidant proteins are likely just a few of many other possible molecules of *C. indrasaksajiae* with powerful antioxidant properties and therefore constitute a natural resource of antioxidant and anti-UV radiation agents (Ruan et al. 2014).

CHAPTER V

The toxic effects of *Chironex indrasaksajiae* (cnidaria: cubozoa) venoms and therapeutic approaches by using copper-gluconate and heat as the treatment and/or inhibitor of venom toxins on sheep red blood cells

1. Introduction

Chironex indrasaksajiae, a chirodropid cubozoan jellyfish that inhabits ocean areas in the Gulf of Thailand, contains cardiovascular, hemolytic, dermonecrotic, immunological, and lethal effects in its venom (Thaikruea and Siriarayapon, 2015b, 2018). It is estimated that approximately seven human fatalities have occurred due to *C. indrasaksajiae* envenomation over the past 15 years. According to case reports, the causes of death are cardiovascular collapse, respiratory failure, or a combination of the two (Thaikruea and Siriarayapon, 2018). The mechanisms behind these phenomena are not yet elucidated. Moreover, box jellyfish venom has developed much attraction for researchers because of its toxic properties that cause death within minutes. The biologically active components of *C. indrasaksajiae* (Thai multi-tentacles box jellyfish) venom and the mechanism of its toxicity have not been studied yet. However, jellyfish venoms are known to be complex mixtures that store in cnidae with several bioactivities such as hemolytic activity, cardiovascular activity, neurotoxic activity and dermonecrotic activity. (Bailey et al., 2005; Bonnet, 1999; Brinkman, 2016; Chung et al., 2001; D'Ambra and Lauritano, 2020; Ramasamy et al., 2003; Ramasamy et al., 2004) Of these all activities, hemolytic activity is considered to play the most basic damage mechanism, and almost all studied jellyfish venoms exhibit strong hemolytic toxicity (Mariottini, 2014). Therefore, this activity is an initial approach to purification or characterization of the venom due to rapid, easily reproducible, and quantifiable procedures.

In this study, hemolytic activity assays were used to test the toxic effects of the venom extracted from isolated cnidae of *C. indrasaksajiae* on sheep red blood cells. Some potential venom components were examined to associate with these biological activities. Due to the detection of protein bands in the molecular mass range of CfTX toxins, I aim to investigate if similar proteins were present in the

venom of *C. indrasaksajiae* using liquid chromatography with tandem mass spectrometry. The CfTX-like proteins were identified in *C. indrasaksajiae* venom that may have similar roles as the CfTXs in *C. fleckeri* venom and explain in part the cytotoxic and cytolytic effects of this box jellyfish venom.

Due to CfTX-like proteins in *C. indrasaksajiae* venom have similar functions to the CfTXs in *C. fleckeri* venom as highly potent and rapid-acting pore-forming toxins (PETs). Box jellyfish venom, according to Yanagihara's hypothesis, includes proteins that break down red blood cells and allow potassium to leak out. As a result of K^+ efflux, the heart's electrical rhythms are disturbed, resulting in cardiac arrest (Law, 2018; Yanagihara and Shohet, 2012; Yanagihara, Wilcox, Smith, et al., 2016). This mechanism that red blood cells being punctured by porin might be the lethal mechanism. Thus, finding the method and blocking composition for treatment and/or inhibiting porin protein should be a primary aim for treatment.

Pore-forming toxins, or porins, are a problematic and fast-acting component of cnidarian venom. Pore-forming toxins are classified broadly according to their secondary structure, with some requiring calcium for self-assembly polymerization to construct functional transmembrane pores (Parker and Feil, 2005). Thus, some divalent cations, including Zn^{2+}, Cu^{2+}, and Mg^{2+}, may compete for calcium-binding sites and disrupt the self-assembly of calcium-dependent porin proteins into functional polymeric pores (Yanagihara, 2013). According to Yanagihara (2019), copper gluconate is ten times more efficient than zinc gluconate alone or in conjunction with copper gluconate in reducing box jellyfish venom-induced cell hemolysis. This study evaluated hemolysis inhibition in *C. indrasaksajiae* venom using copper gluconate.

Furthermore, the widespread hypothesis about how heat can treats cnidarian envenomations is that the temperatures are used to inactivate venom components. Several in vitro and in vivo investigations indicate that cnidarian venoms from all classes within the phylum are heat-labile (Wilcox and Yanagihara, 2016). In this study, *C. indrasaksajiae* venom components were also tested for their inactivation using heat. These findings may have clinical relevance for the treatment of box jellyfish envenomation.

2. Experimental section

2.1 Venom collections

The animal collection was done according to the approved protocol, Mahidol University-Institute Animal Care and Use Committee, and Mahidol University Biosafety Committee. *C. indrasaksajiae* was captured near the coastal zone at Chaloklum bay of Koh Pha-ngan (Suratthani, the Gulf of Thailand) in August 2019. Whole tentacles from live jellyfish samples of mature *C. indrasaksajiae* were manually excised and preserved in 1 M tri-sodium citrate solution (1 volume of tentacles: 9 volumes of citrate solution) and kept at 4 °C, then vigorously shaken for the cytolysis process.

2.2 Venom extraction

Intact cnidae of *C. indrasaksajiae* were isolated and cleaned, similar to the methods described by Yanagihara and Shohet (2012). Excised tentacles were gently rotated in 1 M tri-sodium citrate solution at 4° C until approximately 70% cnidae were recovered by spontaneous release from cytolyzed tentacle tissue. The tentacle solutions were sieved, and the filtered solutions were collected. Sieved (0.5-mm mesh) cnidae solutions were centrifuged at 4 °C at 400 g for 20 min. Undischarged cnidae pellets were resuspended in chilled 1 M tri-sodium citrate at 1:20 (v:v) and washed twice at 400 g for 20 min. The cnidae pellets were then gently transferred to pre-chilled Precellys 24 CKmix lysing kit 2.0-ml tube for venom extraction.

C. indrasaksajiae venom was extracted from cnidae pellets using a bead mill homogenizer (Precellys 24 homogenizer, Bertin Technologies SAS, France) according to the manufacturer's protocol and the method described by Carrette and Seymour (2004) with some modifications. Briefly, 200 mg of cnidae (approximately 750,000 cnidae of *C. indrasaksajiae*) were aliquoted to a pre-chilled Precellys 24 CKmix lysing kit 2.0-ml tube with the mixed of 1.4 mm and 2.8 mm ceramic beads, and 1.4 ml of chilled-sterile water were then added to the tube. Samples were

processed in 6 cycles, each consisting of a bead beating at 5,000 rpm for 15 seconds. Tubes were rested on ice for at least 1 minute between each cycle. Lysates of venom extract were cleared by centrifugation at 10,000g at 4°C for 15 minutes. The viscous supernatant (venom) was snap-frozen in liquid nitrogen and stored at -80°C. Protein concentrations were determined using a BCA protein assay. It was assumed that protein concentration was correlated with venom concentration (Carrette and Seymour, 2004). Measurement of protein using bicinchoninic acid was described by Smith et al. (1985). Albumin was used for protein standards at concentrations of 0, 25, 125, 250, 500, 750, 1000, 1500 and 2000 µg/ml. The samples were read at 562 nm in Infinite M200 PRO microplate reader (Tecan, Grödig, Austria). Prior to the venom activity assay, frozen venom samples were thawed and are referred to as "thawed" venom.

2.3 Hemolytic assays

Sheep red blood cells were used to evaluate the hemolytic activity of the *C. indrasaksajiae* venom. Sheep whole blood in EDTA was purchased from Salaya home animal hospital, Thailand. The packed red blood cells were isolated by centrifugation at 3,500 g at 4°C for 10 minutes. The packed red cells were then repeatedly washed 4-6 times with phosphate buffer saline (PBS) and recovered by centrifugation (3500 x g, 4 °C, 10 min). Finally, RBCs were resuspended in PBS to make a 1% RBC solution for hemolysis experiments. Hemolytic activity assays were performed quadruplicate in 96-well v-bottom microplates. A serial three-fold dilutions of total venom were applied to the erythrocyte suspensions in each well and incubated at 37°C for 1 hour, then immediately centrifuged at 1,000 g for 4 min at 4°C. Next, 150 µL of supernatants will be transferred to 96-well flat-bottom microplates. The released haemoglobin concentration was spectrophotometrically measured at 405 nm and 540 nm using an Infinite M200 PRO microplate reader. Hemoglobin possesses isosbestic points for both its oxygenated and deoxygenated forms, with the large variation in light absorption between the these two forms (Uyuklu, 2011). Total hemolysis was achieved with 5% Triton X-100 as a positive control (100% hemolysis). A negative control (0% hemolysis) was achieved with unexposed 2%

RBC supernatant in PBS. One hemolytic unit (HU_{50}) was defined as the concentration of protein sample required to cause 50 % hemolysis of sheep RBC in 1 mL of a 1% RBC solution at 37°C in 1 hr. The Hemolytic activity (% hemolysis) was calculated using the following equation:

$$\text{Hemolytic activity (\%)} = \frac{OD_{sample}\text{-}OD_{0\%}}{OD_{100\%}\text{-}OD_{0\%}} \times 100$$

Where is the absorbance of the reaction system with venom proteins, $OD_{100\%}$ is the absorbance of the 100% hemolysis control and $OD_{0\%}$ is the absorbance of the 0% hemolysis control.

A significant difference between treatments was analyzed by determining the curved relationship reflecting dose-dependent effects of the two venoms using the GraphPad Prism statistical package version 5.00 (GraphPad Software, USA). The HU_{50} of each species was estimated by fitting log(agonist) vs. response using non-linear regression analysis and was expressed as mean ± SEM (n = 4).

2.4 Ex vivo hemolytic assays to evaluate therapeutic approaches

2.4.1 Using copper gluconate

In 96-well v-bottom microtiter plates, hemolytic activity assays will be performed by adding washed 1 per cent red blood cells (RBC) derived from sheep blood. After thawing frozen *C. indrasaksajiae* venom, three-fold dilutions of total venom were applied to the erythrocyte suspensions in each well. Each well was treated simultaneously with a 1/5 total volume dose of 100 mM copper gluconate to achieve a total final concentration of 30 μM for each well of the treated experiment. After an hour of incubation at 37°C, the microplate was immediately centrifuged at 1,000xg for 4 minutes at 4°C before being analyzed. Next, 150 μL of supernatants will be transferred to new 96-well flat-bottom microplates. The concentration of released haemoglobin was measured spectrophotometrically at 405 and 540 nm using

an Infinite M200 PRO microplate reader. The hemolytic activity, expressed as a percentage of total hemolysis, was determined using the method outlined in section 2.3.

2.4.2 Using heat

Hemolytic activity assays will be performed in 96-well v-bottom microtiter plates by adding washed 1% red blood cells (RBC) prepared from sheep blood. Frozen *C. indrasaksajiae* venom samples were thawed and exposed under different temperature ranges from 0°C (ice bucket), 25°C (room temperature), 37°C (water bath), 45°C (water bath), 60°C (hot plate), and 100°C (boiled water). A serial three-fold dilutions of incubated venom were applied to the erythrocyte suspensions in each well. The microplate was incubated at 37°C for 1 hour before being centrifuged at 1,000 g for 4 minutes at 4°C. The next step is to transfer 150 µL of the supernatants to new 96-well flat-bottom microplates. The concentration of released haemoglobin was measured spectrophotometrically at 405 nm and 540 nm using an Infinite M200 PRO microplate reader. The hemolytic activity (% hemolysis) was calculated as described in section 2.3.

2.4.3 Statistic analysis

The program Prism version 5.00 (GraphPad Software, USA) was used for all analysis of data and statistics. Each concentration-response curve was plotted in triplicate using erythrocytes from one animal. For each turn, the HU_{50} was estimated by fitting log(agonist) vs. response using non-linear regression analysis. The HU_{50} of each experimental condition was expressed as mean ± SEM (n = 4), and multiple comparisons were made by one-way analysis of variance followed by Tukey's test. All tests were considered statistically significant at $p < 0.05$.

3. Results and discussion

3.1 *C. indrasaksajiae* venom activity on RBCs

The protein concentration of *C. indrasaksajiae* venom from bead mill homogenization of cnidae was determined by the method of BCA protein assay and compared with BSA protein concentration standards. The results showed that 200 mg of cnidae (approximately 750,000 cnidae of *C. indrasaksajiae*) homogenized in 1 mL of sterile water contained about 10.67 µg of proteins. The hemolytic effects of *C. indrasaksajiae* venom were examined in the microplate hemolytic assays using sheep RBC. These assays allowed quantitative comparison of toxic venom potency by calculation of HU50 values through colorimetric detection of viable cells and haemoglobin release after venom exposure, respectively. Figure 26 shows dose-response curves of the hemolytic activity of *C. indrasaksajiae* venom. The venom of *C. indrasaksajiae* (0.0003 – 19.7 ng/ml) produced concentration-dependent hemolysis on erythrocytes. Minimum *C. indrasaksajiae* venom induced complete RBC lysis is at 6.58 µg/ml. From the concentration-response curve, the HU_{50} value of *C. indrasaksajiae* venom was calculated as 1.32 ng/ml for 405 nm and 1.96 ng/ml for 540 nm.

Hemolysis is one of the key factors and important effects of cnidarian stinging. It involves the breaking down of red blood cells (RBCs) with the consequent release of haemoglobin (Mariottini, 2014). Our result showed that the venom from the cnidae of *C. indrasaksajiae* multi-tentacle box jellyfish from Thai waters exhibits potent hemolytic activity. Interestingly, in our bioassay, the venom of *C. indrasaksajiae* demonstrated 100-fold more potently hemolytic activity than *C. fleckeri* (HU_{50}) (Brinkman et al., 2014) that, which is currently mentioned as the most lethal animal on the planet (Jouiaei, Yanagihara, et al., 2015; Williamson et al., 1996)

The venom protein components were characterized and identified in chapter IV to find potential toxin proteins that could be linked to the toxic effects. Biochemical analysis of *C. indrasaksajiae* venom proteins revealed that the venoms contained major protein bands of molecular weight between 47 and 57 kDa, which is a larger size than a novel family of bioactive box jellyfish venom proteins (ranging

from ~43 to 51 kDa) (Brinkman et al., 2015). The visualization of protein bands within the molecular range of CfTX proteins suggested suspecting the presence of similar CfTX proteins in the venom of *C. indrasaksajiae*. In *C. indrasaksajiae* venom, the most abundant toxins are *C. fleckeri* toxin-1 (CfTX-1) and toxin-2 (CfTX-2). These abundant peptides reflect the amount of toxin in *C. indrasaksajiae* cnidae venom, suggesting these toxins play an important functional role in box jellyfish envenomation. CfTX-1 and CfTX-2 were also the major toxin protein components in *C. fleckeri* venom (Brinkman, 2008; Brinkman et al., 2012; Brinkman and Burnell, 2008; Brinkman and Burnell, 2007, 2009; Brinkman et al., 2015).

CfTXs are cytotoxic to sheep and human erythrocytes, as well as the smooth muscle cells of the rat aorta. Furthermore, CfTXs have the potential to cause acute cardiovascular collapse and death in experimental animals (Brinkman and Burnell, 2008; Brinkman et al., 2014; Yanagihara and Shohet, 2012). Moreover, there is a significant structural similarity between the N-terminal domains of CfTXs and the N-terminal domains of pore-forming 3d-Cry toxins from various strains of the bacterium *Bacillus thuringiensis*. This suggests that the box jellyfish toxins may have a similar pore-forming mechanism of action in susceptible cells such as cardiomyocytes and erythrocytes (Brinkman and Burnell, 2007; Brinkman et al., 2014; Klompen et al., 2021; Mesa-Galloso et al., 2021). Furthermore, electron microscopy has shown that partially extracted CfTXs from *C. fleckeri* venom cause human red blood cells to develop transmembrane pores (Yanagihara and Shohet, 2012).

Proteins structurally similar to CfTX toxins have been found in the venoms of other jellyfish species belonging to the class Cubozoa. These proteins include CaTX-A from *Alatina moseri* (Nagai et al., 2000a), which was formerly known as *Carybdea alata* Gershwin (2005), CrTX-A from *Carybdea brevipedalia* (Nagai, 2009) and CqTX-A from *Chironex yamaguchii*, formerly known as *Chiropsalmus quadrigatus* (Lewis and Bentlage, 2009). Moreover, homologous proteins to the CfTXs have also been found or predicted in other Scyphozoa and Hydra species (e.g. CcTX-1 from *Cyanea capillata* (Lassen et al., 2011), TX-1 and TX-2 from *Aurelia aurita* (Killi et al., 2020), and CaTX-like from *Hydra magnipapillata (Sher et al., 2005)*). This indicated that homologous proteins to the

CfTXs have been linked to the presence of a specific family of pore-forming toxins (PFTs), described as the most potent cnidarian toxin families currently known (Jouiaei, Yanagihara, et al., 2015). However, some cnidarian jellyfish have no CfTX-like proteins, which may indicate that other venom components such as serine protease inhibitors or metalloproteinases make up most of the venom component in some cnidarians (Banagouro et al., 2022; Yang et al., 2022).

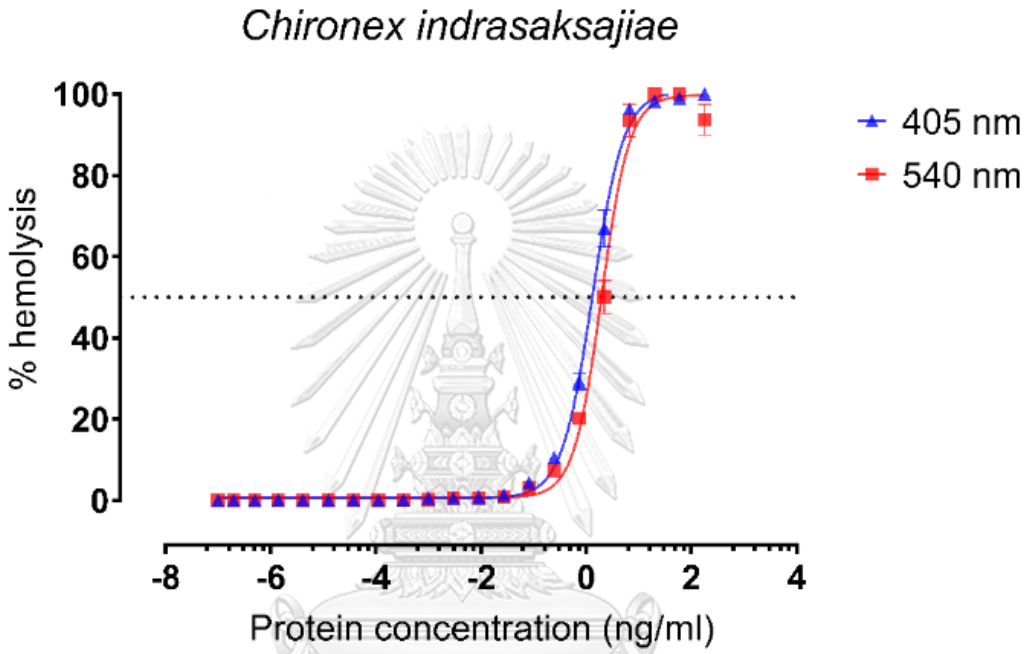

Figure 26 Representative concentration-response curve of the hemolytic proteins. Concentration-response curve of *Chironex indrasaksajiae* venom. All results were representative of quadruplicate experiments and expressed as mean±S.E.M. (n = 4)

3.2 Copper gluconate inhibition of *C. indrasaksajiae* venom

Sheep-washed red blood cells (RBCs) were subjected to *C. indrasaksajiae* venom at a starting concentration of 19.7 ng/ml. These cells were treated simultaneously with a 1/5 total volume dose of 100 mM copper gluconate to achieve a total final concentration of 30 µM. After an hour of incubation at 37°C, the concentration of released haemoglobin was measured spectrophotometrically. As shown in Figure 27, copper gluconate showed the potent inhibitory effect on the hemolysis induced by *C. indrasaksajiae* venom in 1% RBCs. The copper gluconate

inhibited hemolysis of RBCs by a maximum of 81.28 % at the most concentrated dose of 19.7 μg/ml.

The hemolytic toxins (porins) of class Cubozoa are potent proteins that share homology of protein structures with a group of self-assembling bacterial pore-forming toxins that has the ability to alter cell membrane permeability (Yanagihara, 2013). Yanagihara and Shohet (2012) found that the venom of *C. fleckeri* contains proteins that break down red blood cells and allow potassium to be released. The proteins in venom were not only ion channel blockers but also many "porins": proteins that puncture cells, allowing their contents to leak out. The efflux of intracellular potassium as a consequence of hemolysis appears to be the role of a high level of potassium in the blood, or hyperkalemia, that causes the electrical rhythms that keep the heart pumping to be disrupted and the heart to stop beating quickly in mice when injected with high doses of venom. The same happens when mice have only been injected with the porins from the venom. Thus, hemolytic toxins (porins) were suspected as the fatal mechanism.

Bioinformatic analyses revealed that the *C. fleckeri* toxins, CfTX-1 and CfTX-2, which were the most abundant toxin protein found in C. indrasaksajiae venom, belong to a family of potent cnidarian pore-forming toxins. Pore-forming toxins (PFTs), or porins, are the most rapidly acting and lethal components. This protein is the most significant venom component in terms of clinical symptoms. Thus, effective therapeutics for cnidarian envenomation will target the blockade molecules of these pore-forming toxins (PFTs), as well as other membrane perturbance (MPs) (Yanagihara, Wilcox, Smith, et al., 2016). Porin insertion affects the permeability barrier of the cell membrane, allowing monovalent ions to flow. In particular, the efflux of K^+, the influx of Na^+, the influx of Ca^{2+}, and the efflux of CI^- all result in depolarization of the cells due to the rapid equilibration of the internal and external ionic solutions. With enough size and duration of open time, bigger molecules such as intermediates in metabolism (e.g., nucleotides and sugar phosphates) would be allowed to flow out of the pores and cause cell death, also known as pyroptosis, which is represented as a loss of cellular function. Consequently, large proteins such as haemoglobin and lysosomal enzymes leak from red blood cells (RBC), resulting in hemolysis and tissue necrosis (Bashford et al., 1985).

Pore-forming toxins are classified into broad classes based on their secondary structure, with some requiring Ca^{2+} for self-assembly polymerization to form functional transmembrane pores. Because of this, some divalent cations, including Zn^{2+}, Cu^{2+}, and Mg^{2+}, may be able to competitively bind to calcium-binding sites and lead to inhibiting calcium-dependent porin proteins from self-assembling into polymeric pores. In addition, zinc has been reported to have membrane-protective functions in the presence of membrane-disrupting molecules and toxins (MPs) (Yanagihara, 2013).

According to Yanagihara (2019), copper gluconate alone is significantly more effective at reducing venom-induced cell hemolysis than zinc gluconate alone or combined with copper gluconate. In this study, human RBCs were incubated with 5 units/mL/% RBC *Alatina alata* venom, zinc gluconate, and copper gluconate at increasing doses for 1 hour at 37 °C. As a result, it was determined that copper gluconate is active at approximately 30 µM or greater for box jellyfish venom hemolysis inhibition, whereas zinc gluconate is active at approximately 300 µM or greater. Copper gluconate is approximately 10 times more potent than zinc gluconate alone in inhibiting box jellyfish venom. Herein, 30 mM of copper gluconate was also active for hemolysis inhibition of the *C. indrasaksajiae* venom. Moreover, copper gluconate was use as the active ingredients of commercially first-aid treatment for Sting No More™ that was newly developed ex vivo experimental assays for first-Aid approaches by demonstrating that vinegar inhibits nematocyst discharge and that 30 mM copper gluconate-based products inhibit hemolytic activity (Yanagihara, 2013, 2019; Yanagihara and Shohet, 2012; Yanagihara, Wilcox, King, et al., 2016; Yanagihara and Wilcox, 2017). The significant inhibitory effects of copper gluconate-based products on hemolytic activity after cubozoan stinging event represent a novel and effective therapeutic approach for the treatment of cnidarian envenomation.

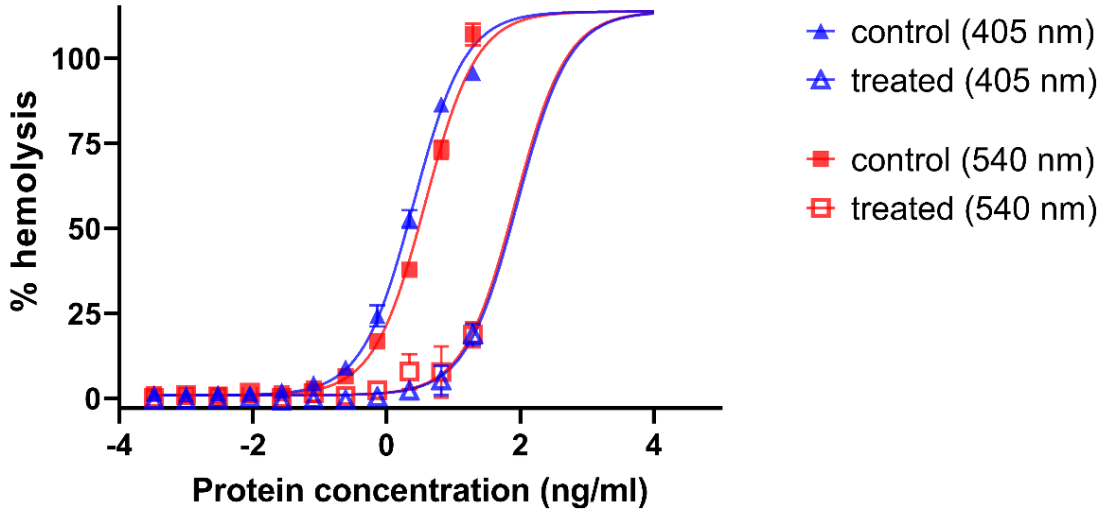

Figure 27 Representative concentration-response curves of hemolysis induced by C. indrasaksajiae venom on red blood cells after treated with copper gluconate

3.3 Effect of heat on the biological activity of *C. indrasaksajiae* venom

Herein, temperatures were utilized in this study to determine the inactivation of *C. indrasaksajiae* venom components. In order to assess the holding temperature effects on the venom independent of temperature effects on the hemolysis reaction itself, temperature pre-incubation experiments were performed. The hemolysis induced by *C. indrasaksajiae* venom in red blood cells of the control group was concentration-dependent and 50% hemolysis was observed at a concentration of ~1.9 ng/mL (section 3.1).

Figure 28 shows the per cent hemolysis observed in the standard sheep blood assay against the log concentration of crude venom protein expressed as ng per ml of the hemolysis assay. Each set of symbols represents assays of serially diluted venom held for 1 hour at a different temperature. The hemolytic activity induced by *C. indrasaksajiae* venom was affected by temperature. According to the graphs, the amount of venom required to cause 50% hemolysis under standard hemolysis assay conditions has changed significantly to the right, indicating that venom potency decreases with higher pre-incubation temperatures.

Hemolytic activity peaked at 0°C and room temperature (25°C). These results indicated applying ice-cold water or an ice pack as a first-aid treatment for *C. indrasaksajiae* envenomation in order to relieve pain or denature the toxin protein by low temperature is not an appropriate approach to handle the situation. Cryotherapy, or immersing envenomed areas in ice-cold water, was previously recommended to improve outcomes in fatal envenomations by delaying the venom's movement into the heart. However, experimental evidence does not support cryotherapy or immersion in cold water for lowering pathology or enhancing clinical efficacy, and this therapy is no longer advised (Frank, 1971; Wilcox and Yanagihara, 2016). According to Yanagihara and Wilcox (2017), heat treatment significantly reduced the size of the hemolytic area in *C. fleckeri* stings, but not as effectively as in *A. alata* stings, suggesting that the venom toxins of the two species have distinct temperature tolerances. Even in the absence of scraping, the application of ice did not reduce the sting area; rather, it dramatically increased its severity, more than doubling the size of the hemolytic zone at 18 hours. Moreover, further research on the impact of ice on

chirodropid stinging is important because there have been documented deaths in situations in which ice was used. (Thaikruea and Siriarayapon, 2016, 2018).

As the results are shown in figure 28, the hemolytic activity was significantly reduced at 37°C and 45°C, but not abolished. At the temperature of 37°C, that is, human body temperature can reduce the activity of venom, indicating after the victim was stung by *C. indrasaksajiae*, our body can partly reduce the hemolytic activity. According to Yanagihara and Wilcox (2017), they defined the term "venom load" as the total amount of venom discharged into sting-site tissues. Due to the fact that less than one per cent of cnidae discharge venom at initial tentacle contact, the researcher has to find a way to remove the attached tentacles, stop the discharged cnidae, reduce the symptoms and the first-aid that are concern in the treatment when dealing with potentially lethal cubozoan stings. Immersion in hot water (45 °C) is a well-established and widely recommended treatment for a wide range of marine envenomations, including severe pain from echinoderm and venomous fish stings (Buckley and Isbister, 2012; Ongkili and Cheah, 2013). Immersing the sting location with hot water is considered to deactivate key components of marine venoms, although the exact mechanism of action remains unclear. Another possibility is that hot-water immersion has a direct potential therapeutic impact on pain receptors, decreasing perceived pain (Muirhead, 2002).

In addition, no activity was observed when the *C. indrasaksajiae* venom was treated at 60°C and 100°C (Table 11), indicating that the toxin responsible for the hemolytic effect is heat-labile. Many researchers suggested that the temperatures required for such inactivation are significantly higher (60 °C), and that the pain relief experienced during hot-water immersion is the result of physiological responses to the heat application rather than a chemical event (such as increased subcutaneous blood flow) (Wilcox and Yanagihara, 2016). Additionally, the widespread hypothesis on how heat treats cnidarian envenomations is that the temperatures were used to inactivate venom components. Several in vitro and in vivo investigations indicate that cnidarian venoms from all classes within the phylum are heat-labile .

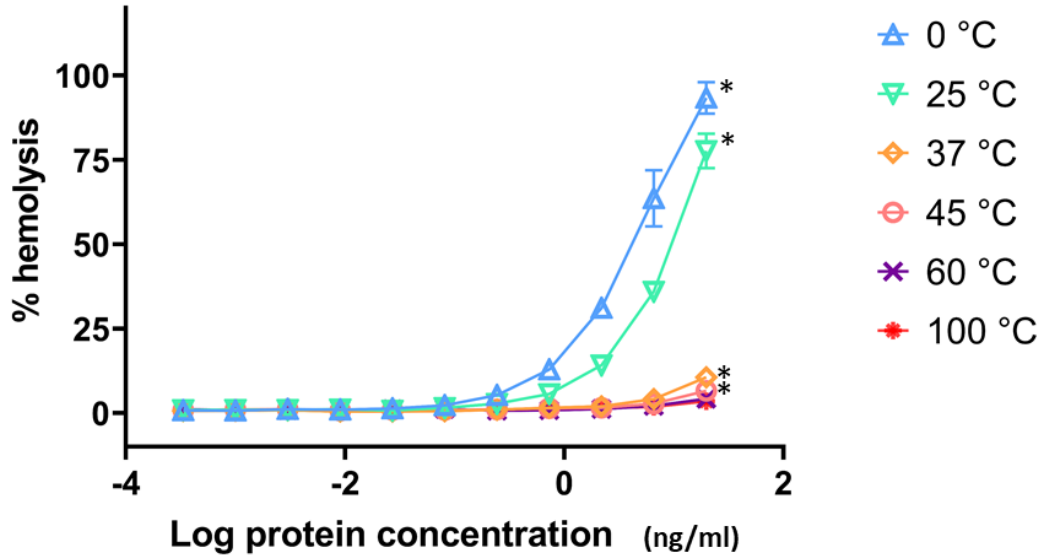

Figure 28 Hemolytic activity of crude venom after pre-incubation at different temperatures. Plot of per cent hemolysis of 1% sheep blood in PBS vs venom protein concentration (log scale). Aliquots of a single extraction of crude venom were held for 30 min at the temperatures indicated, then assayed for hemolytic activity. Arrow indicates 50% hemolysis; the corresponding protein concentration is the HU_{50}. For this and all subsequent figures, experiments were performed in triplicate and mean values with standard errors are shown. Some error bars are within the symbols.

CHAPTER VI
General discussion

1. Introduction

Venomous jellyfish such as the Thai multi-tentacled box Jellyfish, *Chironex indrasaksajiae*, which was just recently described as a new species of box jellyfish from the Gulf of Thailand, inflict painful stings that have the potential to become life-threatening within minutes. These responses are particularly associated with hemolytic and cytolytic reactions. *Chironex* venoms have been shown in several studies to have a wide range of harmful effects on a vast wide range of physiological systems and types of cells. Despite these results, our knowledge of the molecular composition of *C. indrasaksajiae* venoms remains incomplete. This thesis uses proteomics and toxicological bioassays to help clarify some of the present questions surrounding the composition and toxicity of jellyfish venom. Moreover, our knowledge about the known components in *Chironex* species, a porin, a pore-forming protein, is the fast-acting component in the venom. This protein can create pores on the membrane of human red blood cells, making them leak. This leak can release large amounts of potassium ions and may cause cardiac arrest, leading to death. Therefore, this study will be focused on porins activities. Copper gluconate and heat will be tested in the study because these two factors have been reported that the treatments can perturb the self-assembly of porins. This therapy is limited and transient to support cardiovascular hemodynamics. It may allow for more effective therapy.

2. Key findings and their significance

2.1 The cnidome, or census of cnidae in Thai multi-tentacle box jellyfish

C. buitendijki and *C. indrasaksajiae* contain four main types of nematocysts: mastigophores, oval trirhopaloid, euryteles, and isorhizas. However, there are some differences in size, form, and proportion in different species of jellyfish. Moreover, there are differences in the cnidae ratios between two species of Thai multi-tentacle box jellyfish. In *C. buitendijki*, the proportion of mastigophores was less than that in *C. indrasaksajiae*. The proportion of mastigophore is presumably the lethal venom component (McClounan and Seymour, 2012). Mastigophore in *C. indrasaksajiae* shows a remarkable massive to that of *C. buitendijki*. Because of this, the volume of venom content in mastigophores of *C. indrasaksajiae* were higher than that of *C. buitendijki*. Moreover, the length of the mastigophores tubule in *C. indrasaksajiae* was long enough to penetrate the human dermis. Venom would be run off the tubules and passed through capillaries, adding to the quickness with which the envenomation occurs. Thus, the proportion of mastigophores was formerly thought to be the reason for the variation in fatal envenomation between these two species. The difference in fatalities encountered may be due to the percentage of mastigophores, with an increase in *C. indrasaksajiae* proving to be enough to give the lethal dosage as the result of several fatal cases in Thailand, whereas *C. buitendijki* has not.

2.2 Venom extraction for *C. indrasaksajiae*

The schematic design of the extraction procedure for *C. indrasaksajiae* venom is shown in figure 29. Findings from these experiments suggest that although both species are multi-tentacle box jellyfish, the appropriate extraction techniques are different. The possible explanation was that the varying proportions of cnidae types in each species (Figure 20) appeared to result in different venom mixtures that caused the similar extraction process to be inapplicable. Therefore, an appropriate protocol for the extraction of venom from cnidae should be optimized whenever a new species is investigated.

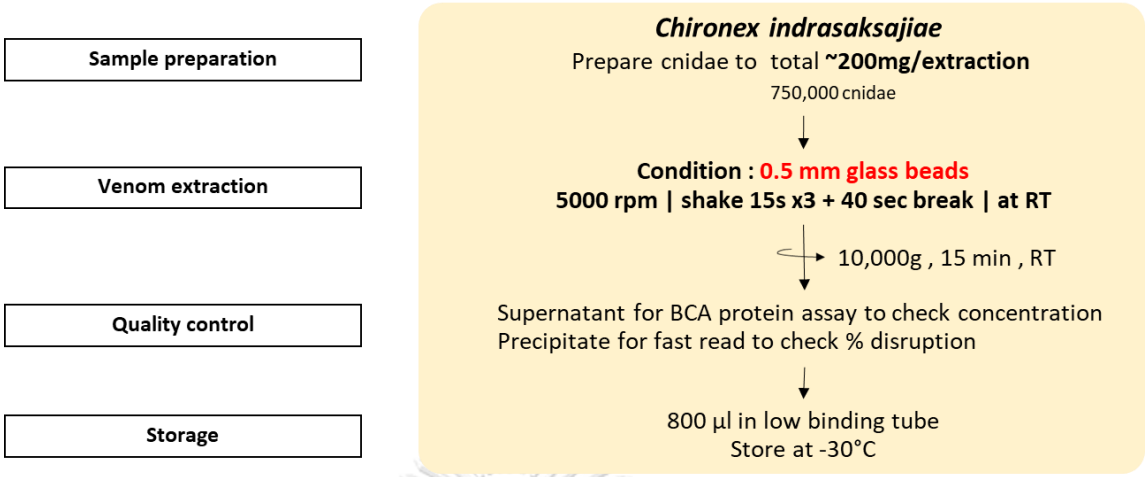

Figure 29 Schematic design of the extraction procedure for *C. indrasaksajiae* venom

2.3 *C. indrasaksajiae* venom composition

The principal aim of this study was to identify proteins in the venom of *C. indrasaksajiae* that could be responsible for its wide range of bioactivities and debilitating effects in humans. As our results show, the venom proteome of *C. indrasaksajiae* contains a diverse array of proteins dominated by toxins and proteins involved in nematogenesis. Due to the lack of genomic and transcriptomic sequences currently available for *C. indrasaksajiae,* the limited cnidarian toxin on the database and *C. indrasaksajiae* is a new species of box jellyfish found in Thai water; it caused the low protein identification rate. The most abundant toxins in *C. indrasaksajiae* venom are CfTX-1, CfTX-2, with sequence coverage of 39.3% and 34.8%, respectively. The CfTX-like proteins belong to a family of potent toxins only found in Cnidaria. Toxicological data and bioinformatic information suggest that this expanding toxin family plays a significant functional role in envenoming. The vast majority of them contained the toxins that contributed to hemolysis. Hemolytic toxic effects that the destruction of red blood cells by pore-forming protein or porin might be suspected as the fatal mechanism (Mesa-Galloso et al., 2021; Yanagihara and Shohet, 2012; Yanagihara, Wilcox, Smith, et al., 2016). Further research is necessary to elucidate the actions of these toxins at the molecular level. Thus, CfTX-like toxin

or C. *indrasaksajiae* toxins (CiTXs) were further studied in genomic and transcriptomic sequences to understand better the molecular, structural and functional diversity of this important toxin family. It will lead to a better understanding of and improvements in medical treatments of cnidarian stings.

2.4 Toxic effects of *C. indrasaksajiae* venoms and therapeutic approaches

Hemolysis is one of the key factors and important effect of cnidarian stinging. It involves the breaking down of red blood cells (RBCs) with the consequent release of haemoglobin (Mariottini, 2014). Our result showed that the venom from the cnidae of *C. indrasaksajiae* multi-tentacle box jellyfish from Thai waters exhibits potent hemolytic activity. Interestingly, in our bioassay, the venom of *C. indrasaksajiae* demonstrated 100-fold more potently hemolytic activity than *C. fleckeri* (HU_{50}) (Brinkman et al., 2014) that, is currently mentioned as the most lethal animal on the planet (Jouiaei, Yanagihara, et al., 2015; Williamson et al., 1996). The toxic effects of *C. indrasaksajiae* have been primarily attributed to CfTX-like toxins, which are highly abundant in the venom. This suggests that these proteins may also be responsible for the toxic effects observed in our *in vitro* assays. Our current understanding of the structure of the venom produced by box jellyfish C. indrasaksajiae is augmented by the discovery of these CfTX-like proteins, despite the fact that further characterization of these proteins is required.

There is no clearly effective specific therapy available. Current treatments are directed at relief of symptoms or, in serious cased, support of cardiovascular integrity after envenomation. Thus, there is a need for effective therapies to reduce the mortality outcomes for cnidarian envenomation. Copper gluconate showed a potent inhibitory effect on the hemolysis (key factors of fatal mechanism) induced by *C. indrasaksajiae* venom in 1% RBCs. The significant inhibitory effects of copper gluconate-based products on hemolytic activity after a cubozoan stinging event represent a novel and effective therapeutic approach for the treatment of cnidarian envenomation.

The hemolytic activity induced by *C. indrasaksajiae* venom was affected by temperature. The amount of venom required to cause 50% hemolysis

under standard hemolysis assay conditions has changed significantly to the right, indicating that venom potency decreases with higher pre-incubation temperatures. The temperatures required for such inactivation are significantly higher (60 °C). Nevertheless, hot-water immersion at 60 °C are unable to apply because the temperature is too high for the skin, and the application of heat might enhance subcutaneous blood flow, which in turn accelerates the spread of venom to the core (heart).

3. Limitations and suggestions for future research

Researchers have developed an interest in the venom of box jellyfish due to its lethal properties, which cause death within minutes. The important and essential phase of venomics is to optimize venom extraction conditions and methods for optimal venom recovery. Researchers have struggled for decades to acquire pure box jellyfish venom stored in millions of cnidae. Due to the difficulties of collecting large volumes of venom from these organelles, several novel approaches for venom extraction have been established. In this study, the approach of Yanagihara and Shohet (2012) was utilized for the isolation and cleaning of cnidae, in which tentacle solutions are gently rotated for several months. The solutions were sieved, and the filtered solutions were collected after around 90% recovery of cnidae. However, cnidocilia attracted to cnidae were still present in the cnidae solution after the fifth cleaning, suggesting that the cytolyzed duration should be extended for all components except cnidae pellets. Cnidae pellets were used for venom extraction using a slightly modified Carrette and Seymour (2004) approach. The outcomes of the experiments that measured the protein concentration of C. indrasaksajiae venom and the percentage of cnidae disruption did not go according to expectations. According to the findings, further investigations into the optimization of venom extraction should involve a variety of parameters in order to get the highest recovery of *C. indrasaksajiae* venom yields. Because *C. indrasaksajiae* is a newly described species of box jellyfish found in Thai waters and there are no specific annotated toxin proteins for this species. Therefore, it is recommended that further research be conducted to construct de novo tentacle transcriptomes in tandem with venom proteomics. Due to

the limited number of annotated toxin proteins in the cnidarian database utilized for the search, the cnidarian database provided 304 toxin proteins, but only eight of those toxin proteins were annotated in the box jellyfish group. These factors contributed to the poor peptide identification rate from LC-MS/MS (Appendix : PTXQC).

Cnidarian envenomations are an important public health problem, responsible for more deaths than shark attacks annually. For this reason, optimization of first-aid care is essential. The findings showed that copper gluconate effectively inhibited the hemolysis generated by *C. indrasaksajiae* venom. However, the copper gluconate concentration utilized in this experiment was too high for intravenous injection. Further study should have been performed on the intravenous injection concentration in order to improve or develop antivenom for preventing deaths from *C. indrasaksajiae* envenomations. According to the findings, *C. indrasaksajiae* venoms and toxins are heat labile at temperatures safe for human application, which supports the use of hot-water immersion of the sting area(s). However, ice packs are often recommended and used by emergency personnel. After performing the experiments, the results do not support for the use of ice in the treatment of C. indrasaksajiae envenomations. This study supports the use of hot-water immersion is a safe and effective method of reducing pain from cnidarian envenomations and is also associated with improved clinical outcomes. These findings may possibly have a role in the treatment of jellyfish stings, however the therapeutic potential for applying heat to treat *C. indrasaksajiae* envenoming is limited. First, these stings can result in death within minutes, and second, heat can produce vasodilation and increase the transport of venom into the circulatory system. However, heat application may be beneficial for other box jellyfish stings in which venom distribution and systemic effects tend to develop more slowly. In the case of Irukandji syndrome, which is produced by some tropical carybdeids, systemic symptoms may not appear until 20–40 minutes after the sting.

APPENDIX

Biohazard Control Plan

The safety precaution or program designed to protect personnel (employees, students), the community and the environment from biohazard.

Safety program includes the following:

- Proper training for personnel
- Provision of equipment for personal protection
- Assign emergency operator and decontamination plan

I. Proper training for personnel

No one is allowed to work with box jellyfish toxin without having prior training by the Principle Investigator who supervised their work.

II. List of primary safety equipment and personnel protective equipment requirements

The following PPE must be worn when working with box jellyfish and its venom, depending on where and which procedures are conducted.

-Field work/underwater work

2mm neoprene thickness full length wetsuit, 3mm neoprene thickness gloves or rubber/silicone scrubbing gloves, 3mm neoprene thickness boots, face shield

-Laboratory

long sleeves lab coat, gloves, surgical mask and eye protection or face shield is required any time because there is a risk of a splash of box jellyfish cnidae/venom outside BSC.

III. Biosafety requirements and procedures

In general, work with box jellyfish must be performed in a BSL2 laboratory. This includes but is not limited to a room suitable for tissue culture with negative pressure and a closing door, and equipped with a certified Class II Biosafety Cabinet (BSC), and a dedicated tissue culture incubator. During

work with box jellyfish toxin, a warning sign must be posted on the door alerting personnel of the presence of box jellyfish venom.

IV. Storage

- Storage of box jellyfish cnidae must be in leak-proof secondary containers at 4˚C.
- Storage of box jellyfish venom must be in leak-proof secondary containers at -80˚C.
- Both cnidae and venom must be clearly marked with a warning label to indicate toxin is present.

V. Waste decontamination and disposal

Decontamination

The box jellyfish tissue or extracted venom will be detoxified/decontaminated by using concentrated detergent/3-5% vinegar/heat then disposed as biohazardous waste. Moreover, we will rigorously inactivate of contaminated surfaces and objects using concentrated detergent.

-Solid waste

Everything that contacts box jellyfish or box jellyfish venom must be decontaminated or contained before disposal. Solid waste can be collected in a biohazard bag. At the end of the work session, the biohazard bag will be closed, sprayed with 3-5% vinegar, and deposited into a biohazardous waste container.

-Liquid waste

Liquid that contacts box jellyfish or box jellyfish venom will be aspirated into container containing concentrated detergent/vinegar. Allowing a minimum time of 30 minutes to inactivate venom. A simple 500 ml bottle with 100 ml concentrated detergent/3-5% vinegar may be suitable to collect liquid waste.

VI. Accidents and spills

- Small spills (<25 ml) can be decontaminate by layering paper towels soaked in 3-5% vinegar on top of the spill, allowing 20 minutes to inactivate venom, then depositing the paper towels in the solid waste bag.
- Large spills (>25 ml) should be treated more cautiously. Warning sign should be post on a door advising personnel not to enter. Notify the PI. In this case, extensive decontamination must be carried out using concentrated detergent.

VII. List of procedures if any accident, injury or illness occurs

1. call for help, if outside the hospital call 1669, if inside the hospital call emergency room
2. pour vinegar over the wound or affected area for at least 30 seconds
3. if unconscious and not breathing/beating, start CPR before pouring vinegar
4. if medical treatment and management is needed follow the Protocol: Expert opinions on jellyfish envenomation especially box jellyfish envenomation (attachment3)

VIII. List specific treatment provision for accidental exposure

- vinegar for decontamination
- copper gluconate spray or cream for specific treatment

  For detailed treatment please see Protocol: Expert opinions on jellyfish envenomation especially box jellyfish envenomation (attachment-2)

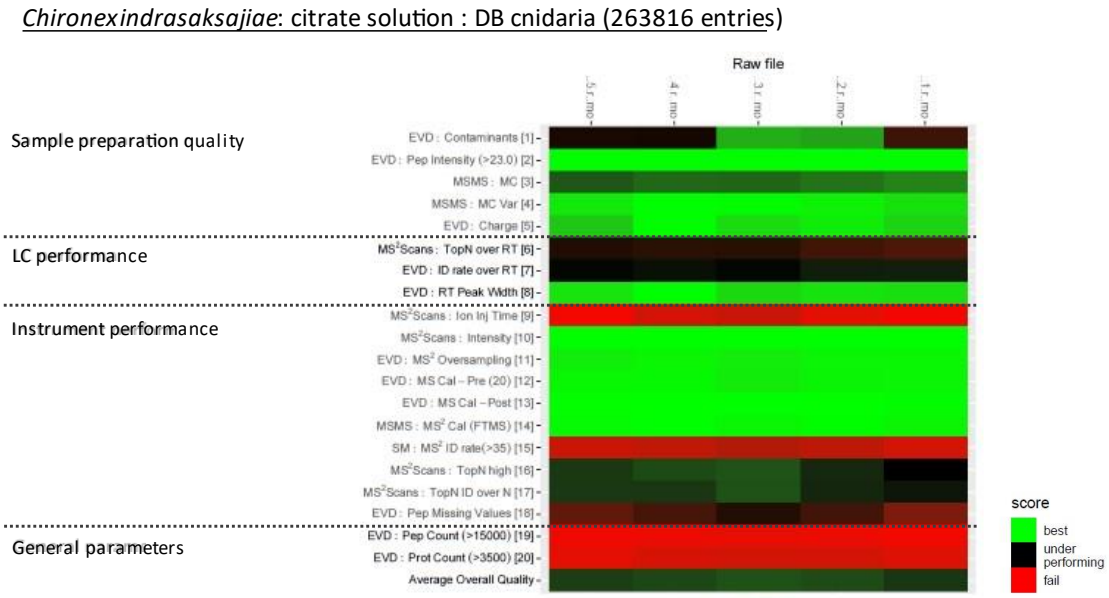
PTXQC Figure 1 Heat map represents the quality of LC-MS/MS analysis



Dataset A1 List of all protein groups identified from *C. indrasaksajiae* venom by LC-MS/MS from the SDS-PAGE gel. Proteins are organized according to the platform LC-MS/MS. All proteins have the percentage of identity in Blast search, Mass (KDa), protein score and the amino acid sequence with the corresponding ion score.

			activity protein threonine kinase activity						
A0A2D4KTV9	Rab GDP dissociation inhibitor (Fragment)	Hemostasis impairing toxin	- GTPase activator activity - L-amino-acid oxidase activity - Rab GDP-dissociation inhibitor activity - GTPase activation	- protein transport - small GTPase mediated signal transduction	*Micrurus paraensis*	Snake	14.018	15.2	48.809
A0A2N1A2B1	MARTX multifunctional-autoprocessing repeats-in-toxin holotoxin RtxA		- calcium- and calmodulin-responsive adenylate cyclase activity - cysteine-type peptidase activity - metal ion binding - toxin activity	Virulence	*Psychromonas sp.*	Bacteria	472.83	0.5	6.2411
A0A670I9L0	Peptidase M12B domain-containing protein	Zinc metalloprotease	metalloendopeptidase activity toxin activity	proteolysis, play roles in cell signaling, cell fusion, and cell-cell interactions	*Podarcis muralis*	Lizard	19.084	4.2	6.7832
A0A0Q4MSR4	Haemagg_act domain-containing protein (Fragment)	Haemolysin	- Cysteine endopeptidases - carbohydrate-dependent haemagglutination activity	Virulence, Polysaccharide metabolism and transport	*Erwinia sp.*	Bacteria	256.14	0.3	6.5401
A0A6N6VWA2	Endotoxin_N domain-containing protein		toxin activity	cytolysis by symbiont of host cells, sporulation resulting in formation of a cellular spore	*Silvanigrella paludirubra*	Bacteria	62.571	1.8	5.7896
A0A2R6EAJ7	Ribonuclease VapC; (Short=RNase VapC; EC=3.1.-.-; AltName: Full=Toxin VapC)	Hydrolase	- magnesium ion binding - ribonuclease activity - toxin activity - Hydrolases; Acting on ester bonds	Toxic component of a toxin-antitoxin (TA) system	*Halobacteriales archaeon*	Bacteria	14.54	14.8	7.844

Accession Number	Protein Identify	Protein type	Protein function	Biological process	Species of Closet	Organism group	Mol. weight [kDa]	Sequence coverage [%]	Score
A0A6P6YCL4	26S proteasome regulatory subunit 6A-B-like	Neurotoxin, Presynaptic neurotoxin	ATP binding, proteasome-activating activity, toxin activity	exocytosis, protein catabolic process	*Dermatophagoides pteronyssinus*	Dust mite	86.209	2.2	6.432
A0A1B1LHQ5	Putative insecticidal binary-like toxin		- Insecticidal crystal toxin - toxin activity	Virulence, modulation by symbiont of host defense response	*Bacillus thuringiensis*	Bacteria	41.341	1.7	8.1739
V7IBB3	Toxin CdiA	Haemolysin Polymorphic toxins	- toxin activity	Virulence	*Eikenella corrodens*	Bacteria	345.5	0.6	7.2283
A0A2D3TFQ5	Peptidase C80 domain-containing protein	Metallopeptidases	- cysteine-type peptidase activity - metal ion binding - autolytic activity - toxin activity	Autolysis, Virulence, Toxin causes actin crosslinking which leads to depolymerization and rounding of cells	*Candidatus Hamiltonella*	Bacteria	198.59	1.2	8.0899
A0A6J1TPU2	F-actin-monooxygenase MICAL2	Hemostasis impairing toxin	actin binding, FAD binding, L-amino-acid oxidase activity, metal ion binding, monooxygenase activity, NADPH:sulfur oxidoreductase activity	actin filament depolymerization, positive regulation of transcription via serum response element binding	*Notechis scutatus*	Snake	209.12	0.4	6.0442

VITA

NAME	Miss Chanikarn Yongstar
DATE OF BIRTH	14 April 1995
PLACE OF BIRTH	Trang province, Thailand
INSTITUTIONS ATTENDED	Satri Thungsong School, Thungsong, Nakorn Si Thammarat 2008 - 2014 High School Certification School of Science, Walailak University 2014 - 2017 Bachelor of Science (Computational science) Major : Computational Biology. GPAX 3.67 Department of Marine Science, Faculty of Science, Chulalongkorn University 2017 - now Master of Science (Marine Sciences) GPAX 3.92
HOME ADDRESS	109/9, village no.2, Thumyai sub-district, Thungsong district, Nakorn Si Thammarat, Thailand, 80110
PUBLICATION	Mini Project Comparison of Subtidal zone and Intertidal zone with the densities of zooxanthellae in Porites lutea Co - authors: Nattapat Chaisimaneepan, Pornchanok Veereeyanun, Pannarai Pannasiri, Ratchapon Pluekaom, Pimpa Muangsorn The 24th Marine Ecology Summer Course 2016 Phuket Marine Biological Center (PMBC) Research Paper THE GENUS Pelagia (SCYPHOZOA) FROM ANDAMAN SEA Chanikarn Yongstar1, Charatsee Aungtonya2* and Udomsak Darumas1 1 School of Science, Walailak University, Nakhorn Si Thammarat 80161, Thailand 2Phuket Marine Biological Center, P.O. Box 60, Phuket 83000, Thailand Proceedings : การประชุมวิชาการวิทยาศาสตร์ทางทะเลออนไลน์ เพื่อสนับสนุนทศวรรษแห่งสหประชาชาติว่าด้วยวิทยาศาสตร์ทางมหาสมุทรเพื่อการพัฒนาที่ยั่งยืนปี ค.ศ. ๒๐๒๑-๒๐๓๐ เรื่อง การศึกษาวิธีการที่เหมาะสมในการสกัดและองค์ประกอบเบื้องต้นของพิษแมงกะพรุนกล่องหลายสายในประเทศไทย: Chironex indrasaksajiae

และ Chiropsoides buitendijki
